TROW'S
PRINTING AND BOOKBINDING COMPANY,
201–213 *East 12th St.*,
NEW YORK.

LIST OF CONTRIBUTORS TO VOL. XVII.

Ady, Dr. A., West Liberty, Iowa.
Agnew, Dr. C. R., New York.

Bacheler, Dr. H. M., Gaboon, W. Coast of Africa.
Baruch, Dr. S., Camden, S. C.
Benson, Dr. G. E., Hudson, N. Y.
Beard, Dr. George M., New York.
Berry, Dr. John James, New York.
Bigelow, Dr. Horatio R., Washington, D. C.
Billington, Dr. C. E., New York.
Blake, Dr. John Ellis, New York.
Blodgett, Dr. A. N., Boston, Mass.
Bogert, Dr. S. S., New York.
Bosworth, Dr. F. H., New York.
Bothz, Dr. Carl, New York.
Bozeman, Dr. N., New York.
Briddon, Dr. Chas. K., New York.
Bridge, Dr. Norman, Chicago, Ill.
Bristowe, Dr. J. S., London, Eng.
Brown, Dr. L. Austini, U. S. N.
Bucklin, Dr. C. A., New York.
Bullard, Dr. G. B., St. Johnsbury, Vt.
Burrall, Dr. F. A., New York.
Byrd, Dr. Wm. A., Quincy, Ill.

Campbell, Dr. Robert, New York.
Carlile, Dr. S. D., Palmyra, Ill.
Carpenter, Dr. Wesley M., New York.
Carroll, Dr. A. L., New Brighton, S. I., N. Y.
Chamberlain, Dr. C. W., Hartford, Conn.
Cheesman, Dr. H., New York.
Clark, Dr. A., New York.
Clark, Dr. James G., West New Brighton, N. Y.
Colvin, Dr. D., Clyde, N. Y.
Comegys, Dr. C. G., Cincinnati, O.
Conn, Dr. G. P., Concord, N. H.
Coues, Dr. Elliott, U. S. A., Washington, D. C.
Cooley, Dr. Jas. S., Sandy Hill, N. Y.
Cowling, Dr. Richard O., Louisville, Ky.
Cutter, Dr. Geo. R., New York.

Da Costa, Dr. J. M., Philadelphia, Pa.
Dalton, Dr. John C., New York.
Daly, Dr. W. H., Pittsburg, Pa.
Dana, Dr. C. L., New York.
DeGarmo, Dr. W. B., New York.
DeLuna, Dr. A. B., New York.
Dean, Dr. M. H., Wampum, Pa.
Deaton, Dr. V. S., Alcony, Ohio.
Donnelly, Dr. M., New York.
Doyle, Dr. Gregory, Syracuse, N. Y.
Duncan, Dr. W. F., New York.
Dundas, Dr. Thos. A., Elmira, N. Y.

Fehr, Dr. Julius, Hoboken, N. J.

Original Lectures.

THE THERAPEUTICAL ACTION OF COLD.

A LECTURE BY

W. H. THOMSON, M.D.,

PROFESSOR OF THERAPEUTICS AND MATERIA MEDICA IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

GENTLEMEN:—Remedial agents are of two kinds: First, drugs; and second, other therapeutic measures, such as temperature, electricity, etc. For the sake of convenience, we will here consider those remedial agents which are not drugs, and first, among them, we will study one of the physical forces or imponderables—cold.

Physically, cold is the absence of heat. Therapeutically, it is a positive agent, and has five actions:

1. Tonic.
2. Styptic.
3. Antiphlogistic.
4. Anæsthetic.
5. Antipyretic.

In the first three, cold acts only upon the vaso-motor system as a pure irritant neurotic. In the last two it acts simply on physical principles.

COLD AS A TONIC.

We have said that cold, when it acts as a tonic, is an irritant. Every irritant produces a shock and causes an expenditure of the energy of the part irritated. The energy of the part irritated, therefore, becomes depressed; but this depression differs from that produced by a simple sedative, in that it is followed—provided the shock is not so great as to cause exhaustion—by a *reaction* to or beyond the condition in which the part was prior to the irritation. Thus, cold, as an irritant, affects the vaso-motor system and produces a shock which is followed by a reaction. In other words, this system is exercised, and all moderate exercise tends to strengthen the organ called into action, and permanently to improve its nutrition. Cold, then, is a vascular tonic, and may be used generally or locally. When the circulation is feeble, and there is loss of muscular power, the general use of cold will arouse the heart, restore arterial tone, and thereby improve the nutrition of the whole body. For this purpose either the dip-, shower-, or sponge-bath may be used, according to the strength of the patient, taking care never to cause exhaustion by its too frequent or too protracted use. A thorough reaction, as indicated by a glow of the skin, should always follow the bath, and never a sensation of lassitude or fatigue. When the irritant effect produced by the cold water alone is not sufficient, salt or some mild rubefacient may be added. If the patient is too feeble to bear even the sponge-bath, simple exposure of the surface of the body to cold air will often prove beneficial. In all cases reaction may be assisted by friction with a rough towel.

A cold douche to the nape of the neck is indicated in the following conditions:

1. When, after sunstroke, the arteries of the head remain dilated, and there is headache and dizziness on exertion or exposure to the sun.
2. In all cases in which headache is confined to one side, and is attended by dilatation of one temporal artery and suffusion of one eye.
3. In false croup, or the crowing respiration of children.
4. In tinnitus aurium, when the throbbing is synchronous with the beating of the heart, and the tympanic arteries are distended, the cold douche to the nape of the neck, aided by the internal use of hydrobromic acid, may afford relief.

Sponging the chest of a phthisical patient with cold water lessens the susceptibility to cold.

Local applications of cold water are useful in promoting absorption of inflammatory effusions and exudations in the subacute and chronic stages; also in restoring the balance of the circulation in the liver and spleen when enlarged in malarial poisoning.

The hip- or sitz-bath is useful in hemorrhoids, prolapse of the rectum, and congestion of the pelvic viscera.

COLD AS A STYPTIC.

As a styptic, cold acts by constringing the arteries through its influence on the vaso-motor nerves. It is preferable to astringent drugs or other hæmostatics, because it obviates the necessity of applying irritant substances to the bleeding part. Nor need the cold always be applied directly to the seat of the hemorrhage; for it will also affect distant parts in accordance with the laws of the vaso-motor system, the most important of which are the following:

First.—An impression on the afferent nerves of a given part will cause a variation in the calibre of the arteries of that part.

Second.—An impression on the afferent nerves of a given part will cause a variation in the arteries of all organs situated directly beneath that part.

Third.—In the case of organs which are in pairs and perfectly symmetrical, as the eyes, ears, hands, and feet (the lungs, kidneys, and testicles are not), variations in the calibre of the arteries of one will cause a similar variation in the other.

Fourth.—Variations in the calibre of the arteries of certain parts are accompanied by corresponding changes in the arteries of certain other parts, and these particular associations are to be determined by experiment: for example, the relation between the circulation of the feet and that of the pelvic viscera and the pharynx, and the relation of the circulation at the nape of the neck to that of the head and face.

The following instances will suffice to illustrate the application of these laws in the use of cold:

1. Cold water applied directly to a bleeding surface.
2. Ice-bags to the epigastrium to check hæmatemesis.
3. Holding any cold body in one hand to arrest hemorrhage in the other.
4. Cold foot-baths to arrest metrorrhagia.

In post-partum hemorrhage the best means of applying cold is by ether spray, for the sudden and intense impression produced causes effectual contrac-

tion of the uterus without chilling the patient. If ether spray is not available, cold water should be poured upon the abdomen from a height of two or three feet, the shock of the falling water materially assisting the action of the cold. Either of the above measures may be used for hæmoptysis.

COLD AS AN ANTIPHLOGISTIC.

As an antiphlogistic, cold may be used to arrest an acute inflammation, unless suppuration has occurred, or to prevent inflammation when threatened. This it does by causing a protracted constriction of the arteries, thereby preventing the active congestion essential to all acute inflammation. It should be invariably applied as dry cold, directly to the part affected, in sufficient intensity to relieve pain, and continued so long as the exciting cause exists. If, before the tendency to inflammation has entirely disappeared, a neuralgic pain occurs, it is a sign that the vaso-motor nerves have become exhausted, and the use of cold must at once be discontinued, or gangrene will result; moreover, the patient will feel more comfortable without than with the cold applications. This neuralgic pain is continuous, and, if the injured part be one of the extremities, it extends from the part injured toward the trunk. Inflammatory pain, on the other hand, is local throbbing, accompanied by local heat, and is relieved by more thorough applications of cold. In fractures, or other severe injuries near joints, the injured parts should be surrounded with pounded ice placed in pigs' bladders or rubber bags, two or three layers of perfectly dry muslin being placed between the skin and bags, lest the parts be chilled too suddenly. A bottle filled with ice-water makes a good antiphlogistic splint for injuries of the hand. Inflammation of the eyes may be controlled, and its spread from one eye to the other prevented, by means of cold applications. Ice-bags should be applied to the head and spine in epidemic cerebro-spinal meningitis. Cold applications will control the spread of erysipelas, and are the best means for relieving febrile headache. Headache from uterine trouble is best relieved by moist warmth. Cold should not be used antiphlogistically in any acute inflammation of internal organs except peritonitis with vomiting, and meningitis.

COLD AS AN ANÆSTHETIC.

The use of cold as an anæsthetic depends upon its physical property of freezing tissue and deadening sensation without injuring vitality. It is most useful in operations where no great thickness of tissue is involved, as in opening abscesses, amputation of fingers, Cæsarean section, and ovariotomy. In all cases the action of the cold should be secured as rapidly as possible. Apply ether spray to the part alone which is to be operated upon. Anæsthesia is complete as soon as the skin becomes white and glistening.

COLD AS AN ANTIPYRETIC.

When the abnormal elevation of the bodily temperature is due to insufficient radiation of heat, as in some nervous disorders, it is not generally in itself dangerous; for it has been known to reach 123° F., and remain there for several weeks. But if, as in fevers, the rise of temperature depends upon excessive chemical changes, then the heat itself is injurious, causing arrest of gland-secretion, as well as extensive destruction of tissue. In every fever there is a certain point beyond which, if the temperature rises, certain structural changes will take place. The glands become affected with cloudy swelling, and fatty degeneration ensues, and the muscles affected in the same manner become remarkably brittle.

The point at which these changes occur differs in each fever. In scarlet fever it is 105° F.; in typhoid fever 106° F.; in relapsing fever from 107° to 108° F.; and in erysipelas still higher. Beyond this dangerous point in each fever the temperature should not be allowed to rise, but must be lowered by the use of cold, the result of which is simply the abstraction of heat. This may be effected by immersion in a cold bath or by the cold pack. Place the patient in a bath at 75° F., and gradually cool the water down to 65° or 60° F.—never lower, and at the same time use cold affusions to the head continuously. At first the temperature will rise slightly, owing to the blood being driven from the surface of the body into the viscera, which are always a little warmer than the skin; but the bath should be continued until the temperature is reduced to 100° F., provided the fall is gradual—that is, one degree in six, five, four, or three minutes. If it falls one degree in two and a half minutes, stop the bath when the temperature has reached 101° F.; for in most cases a further reduction of one degree will occur after the bath is discontinued. If the fall in temperature during the bath be one degree in *two* minutes, the patient should be taken out at once, whatever the actual temperature may be; for in such cases there is danger of the subsequent fall becoming uncontrollable, reaching perhaps 97° F., and the patient passing into collapse. Should this at any time occur, wrap the patient in hot blankets, apply hot saucers to the epigastrium, and give brandy or other stimulants.

When, for any reason, the bath is impracticable, the cold pack may be used, always, however, with the same precautions as in the use of the cold bath. First wrap the patient in a sheet wrung out of water at an ordinary temperature, say 70° F., and then lay on other sheets wrung out of ice-water. The cold bath or pack should be repeated often enough to keep the temperature below the point of danger for that particular disease. If necessary, use one every hour. If, however, two or three a day are sufficient, one should be so timed as to be given just before the highest rise of the fever-heat—that is, usually between two and three o'clock in the afternoon.

The contraindications to the antipyretic use of cold are hemorrhage from the bowels and notable variations of temperature from the regular course. Bronchitis and pneumonia are not necessarily contraindications.

INJURY OF EYES FROM CHLORAL.—Dr. G. H. Felton, of Haverhill, Mass., writes: "An instance has just come to my knowledge in which two young ladies, sisters, suffered injury to the eyes from the use of chloral. I did not ascertain the amount used, but it was apparently administered in the usual small doses, and continued only a very few days. The eyes in both cases became extremely painful, compelling the patients to remain several days in a dark room, and a permanent weakness remains (after two years), requiring the occasional use of colored glasses, and greatly impairing the usefulness of the eyes. Has chloral ever before been known to produce a similar effect?"

CLIMATE CURE IN NERVOUS DISEASES.

A Lecture Delivered before the Providence Medical Association, Nov. 3, 1879.

By WILLIAM F. HUTCHINSON, A.M., M.D.,

late passed asst. surgeon u.s.n.

Gentlemen:—I am to address you this evening upon what I term "climate cure" for cases of diseases of the nervous system. The various sanitaria of the globe have been the resort of invalids ever since the most remote historic ages, and in so far as diseases of the respiratory tract are concerned, every known resort has been carefully investigated, tabulated, and published. Every one knows or can readily ascertain, by reference to records close at hand, the air pressure, the temperature, and the amount of moisture in the atmosphere of almost any of them—and, furnished with these data, can apply them to individual cases with more or less success. But I hope to be able to show you that something vastly different from this is essential when we come to consider the protean forms of nerve derangement.

As a majority of the diseases above referred to are usually the result of lack of nutrition, it will be evident that remedial measures must be such as tend to promote an increase of assimilative power—a better metamorphosis of certain elements of food into nerve cells. Now, while tonics and stimulants play a leading part in the treatment of these ills, it is only as adjuvants that they can be useful, when the assimilative functions lie dormant by reason of general nerve exhaustion. It is the fashion to prescribe bitter preparations of steel and bark, of strychnia and phosphorus, of alcohol and chloral, until the wearied stomach rebels, and will stand no more. And, when the most eminent authorities in the profession have made themselves widely heard in favor of a different course, there can be but little excuse for a continuance in the same routine of treatment that obtained twenty years ago. The chief trouble with our physicians seems to be that this matter of climate cure is very generally overlooked, or, at best, but cursorily glanced at. Patients are sent to the sea who should go to the mountains; those needing thin, highly oxygenated air, to the sea; patients who have not vitality enough to stand the freezing-point of Fahrenheit go to Minnesota, and those whose lymphatic temperament and plentiful adipose tissue would stand any amount of cold, are directed southward. In too many cases such advice, as blindly followed as given, proves but the finger-post to another world. I have seen case after case of tuberculous lung sent to the soft moist air of Florida or Nassau, and result fatally, which would, in all human probability, have taken a different course in an inland climate—one at the same time dry and warm. It should be constantly borne in mind that an elevated temperature is by no means the most important point to consider; that it is the dew-point, the saturation level of the atmosphere which needs to be kept steadily under observation. Broadly speaking, keep patients suffering from pulmonary disease in thin dry air, and nerve invalids in heavy moist air.

The sea air, far from land, often puts to rest neuralgias and nerve-tire, and effects the final cure of the patient. We commend the sea voyage.

Avoid the rail! When surrounded with every comfort possible even to a Pullman car, its disadvantages are numerous and great. Rest there is none, nor proper food, and sleep comes only when sheer exhaustion compels it. Give me two patients bound, let us say, to Southern California, one of whom shall go by rail and the other by the Isthmus route, and the difference upon arrival will be wonderful. During the sea trip of four weeks, with the daily increasing comfort which familiarity with ship-surroundings gives, with the glimpses of tropical life caught at Panama and up the Mexican coast, with regular meals and regular sleep, improvement is rapid and thorough.

It is my desire to present here, with all possible force, the necessity of physicians speaking upon all points connected with climate cure, from actual experience, or of refraining from speaking at all. With men present in every large community whom years of travel and experience have made familiar with the important points in climate cure, there should be no danger of misdirection; and if I am successful in impressing upon you the fundamental truth of the necessity of investigating thoroughly the points for and against any specified resort, I shall be content. Books on climate tell us but little: they are usually compilations of statistics and figures made by some non-professional observer; and a single visit by an intelligent physician to Minnesota in winter or to the West Indies, is worth more to him than a decade's record of temperature, barometric or hygrometric pressure alone. When we read of certain average barometric pressure and range of temperature, accompanied by the dew-point for the same time, nothing seems easier than to settle in one's mind: "That is just the place to send Mr. J.! Exactly the climate for his weak lungs!" But if you will accompany Mr. J. to the enviable locality, you may find how easily figures can mislead. A thousand subtle influences which are utterly beyond instrumental measurement—a thousand seeming trifles, of which you cannot know except by personal investigation—frequently more than nullify the advantages which you hoped to secure to him by the change; and when Mr. J. returns he is worse.

Last spring, one of our physicians placed under my care a lady who had been for twenty years a sufferer from that very prevalent American disease, neurasthenia—nerve-tire. She had been under the care of various eminent practitioners all this time, and, shortly after her first visit, brought with her a file of copies of prescriptions, which was a curiosity in its way. Every preparation of iron; of cinchona bark and its alkaloids; of strychnia and its compounds; of phosphorus; of cod-liver oil and its emulsions; in fine, of every substance, animal, vegetable, or mineral, which is known or thought to possess a specific influence upon the nervous system, was therein represented. The poor lady told me that, having accumulated quite a stock of these drugs, she would frequently take several kinds in one day, hoping—to use her own words—to hit the mark with some one of them.

The trouble was, there was no mark to hit. The assimilative glands were paralyzed, and the only effect of a continuance of such a regime, must of necessity have been harmful. As she could not then leave the city, I directed her to stop at once all forms of medication, to confine herself strictly to a skim-milk diet, and commenced daily applications of a very fine faradic current over the head and upper part of the body. Nothing was so difficult for her to do as to relinquish the old habit of taking medicines, and she would nightly beg her husband, in piteous tones, for her beloved drugs. But he resolutely seconded

ity effects, commencing by consuming to the flame the dome the pharmacy, and she was already gleaming when, a few weeks later, I advised her to go to New port for the summer. Now she is returned—after a season at the sea-shore—after regular salt baths and open air exercise, and after four months rigid adherence to a milk diet—so much changed for the better as to be scarcely recognizable. In passing, I may say that I consider Newport one of the very best summer climates for nerve invalids in the world. Its advantages are too numerous to even allude to—its chief drawback being that one's purse is depleted there with an ease and rapidity which startles the unaccustomed visitor.

Since 1858 I have devoted a portion of every year to travel; and for the last six years, in company with a small number of patients—nerve invalids all—we have sought such lands as seemed best suited to our needs, and in one instance only has the change of climate failed to be of benefit. The changes thus wrought, often by single voyages, are due to rest and the subtle influences of total change. Rest, enforced by the confined precincts of the ship, and made sanative in a high degree by ocean breezes—rest from business cares and worries, from home duties and home-work.

All the functions of life—notably those peculiar to women—are performed with great regularity at sea, after the preliminary fillip of sea-sickness, and no appetizers are necessary. A good ship, attentive service, and first-class fare, are imperious necessities, and I am glad to say that our leading coast lines now leave but little to complain of in these matters.

The journey should be a sufficiently long one. If the patient be a man of business who has torn himself loose from great interests with infinite difficulty, the advent of a daily mail laden with requests for advice or solutions of troublesome details, or the presence of a telegraph station with its possibilities of instant communication with cares which should be left behind, are disturbing factors in our scheme of cure. It is better to get entirely beyond their reach, or, at least, far enough away to make any idea of return before the appointed time, entirely out of the question. No news is good news, and the proverb loses its triteness when once you swing clear of the great channels of communication of the world.

It is better not to go alone. Even if acquaintanceship is not made until arrival on shipboard, the knowledge of common interest, of a common object to be attained, speedily produces a warm cordiality, which often ripens into friendship. Then, too, it is much less expensive for a party than for a single person.

It should be borne in mind that there is no more exhausting work in the world than sight-seeing. Nerve and muscle alike give way under the heavy burden, and the brain cannot properly care for impressions which succeed each other so rapidly. For this reason, I rarely recommend European resorts to nerve invalids. There are none of them that can be reached without traversing one or more of the world's great capitals, whose attractions are much too strong to be withstood; and the steady strain of a week in London or Paris has more than once proven irremediable.

There are comparatively few places in the world which offer advantages to the nerve invalid sufficiently unbalanced by discomforts, to which we may send them, and none within the limits of the Eastern United States where a winter residence is to be recommended. Our climate is too dry, too changeable, as a rule, and the lack of adipose tissue, which is almost a distinctive feature of the American, as well as his peculiar nervous manner, attests the fact. In New England heredity plays a prominent role in transmitting tendencies in this direction. We are for the greater part descended from generations of pork and pie-eating ancestors, whose idea of correct living was continued to the indispensable task of satisfying hunger, and it was esteemed a virtue to do this in the most expeditious and cheapest way. The blood, which was thus rendered impure, continuing to be impaired by a continuance of like diet, was incapable of resisting malign or adverse climatic influences; and it is certain that, either from this or some unknown reason, New England people suffer in a larger ratio from nervous diseases than residents in the West and Southwest. So it is essential, in advising climate cure, to make as radical a change as space and time will permit, studying the idiosyncrasies and possibilities of each case separately.

For a summer home there is none equal to our own Newport. The heavy sea-fogs, which are sometimes complained of, are in themselves most active agents in quieting irritable nerves. Its amusements, in the way of boating, riding, and reading-rooms, are unsurpassed. It is too near the centres of trade and toil to permit freedom from business annoyances to be secured, and it is difficult to remove the effect while the cause remains. Still, taken all in all, it is undoubtedly the best place in North America to which we can send a nerve invalid for a summer residence. Next to Newport should be placed Old Point Comfort. It has a few decided advantages over the first named, in that, being further south, the season is prolonged, and the early autumn much less changeable, and that it is a little farther away. Another item is its comparative cheapness. But, aside from these two places, it matters little where on our Northern sea-coast the summer home is chosen. It is difficult to go wrong if one does not go south of Virginia. These remarks apply with equal force to the Pacific coast. From Seattle on Puget Sound, to Tacahuama in Southern Chili, there are four places only which are used for summer resorts, and, as these in nowise differ from our nearer stations, they may be passed. The summer is not the time of trouble.

It is the winter resort which is most needed, and the question is, Where shall we send them then? Within easy reach of our shores, I know of but three places combining the requisite qualifications, namely, Bermuda, the Bahamas, and the Windward Islands. Off the Pacific coast there are the Sandwich Islands, making in all four resorts, which I propose briefly to review in turn. The Azores and Canaries are placed out of the category, by reason of irregular, indefinite communication and utter vacuity of everything but climate after getting there. The Bermudas, our nearest neighbors, naturally come first. Distant only about six hundred miles from our coast, easily reached by a weekly line of steamers from New York, with one first-class hotel, the Hamilton House, and numerous private boarding-houses, they offer many attractions. The climate is good, its winter range, however, being a little too low for our invalids—60° to 66° Fahr.—while the islands are swept by constant breezes. There is a great number of islets in the group—some five hundred in all—but only one of them (St. George's) is of any importance, and is the military station of the colony, as well as the winter naval station of Her Britannic Majesty's North American Squadron. Owing to the curious shapes

of some of the islands, and the numberless channels which coral zoophytes have wrought between them, boating is almost as necessary as in Venice, and offers to the visitor constant and healthful amusement. But this and occasional impromptu entertainments by the officers of the station and their friends, are all the amusements to be had, and it is but a short time before anticipation of the steamer-day is the staple topic of thought and conversation. There is another drawback, which is more serious. Owing to its position far from any main-land, the dew-point is high, the atmosphere fully charged with saline vapors. This, in itself almost a *sine qui non*, is rendered an objection by reason of the very frequent high winds, which are sufficiently rapid to make outside exercise uncomfortable, and at times almost impracticable for women, on account of the driving salt mist. During the winter of 1877–8, I had several patients there who came home no better than they went, and various visits to the islands have convinced me that the main trouble was too low temperature with too much high wind.

The Bahamas come next, and, in my opinion, offer to the East American public the most valuable health resort in the world, if cases sent there are only carefully selected. The temperature is just right—70 to 75° Fahr.—with a remarkably small diurnal range of variation—rarely more than three or four degrees; its dew-point high and steady; its streets clean, with perfect drainage through the interstices of the coral from which all the islands are formed, and the society of the principal city, Nassau, remarkably good for a tropical colony. Its hotel, the Royal Victoria, is a fine building, comfortable in all its appointments, but, under its present management, is ill-kept and anything but attractive. Private boarding-houses, where prices range from nine to twelve dollars a week, are numerous and excellent. As for amusements, they are plentiful. No one can tire of sailing in the beautiful harbor, nor of driving through the island forests of native pine. There is no time of the day or night, except an hour just after sunset, when visitors may not wander at will through the white streets, or row about upon the green water of the harbor. The disadvantages are, that all meats and most vegetables are supplied from New York, and are not always either plentiful or good. If one is content to live upon couch food, as native diet is termed, he would do far better than at the hotel, as it is under the entire control of an utterly incompetent landlord. The sunglint is great and strong. As the streets are merely troughs cut in the white coral, and as the sun is almost never beclouded, the glare is very trying to strong eyes, and dangerous to weak ones. Patients should not go to the Bahamas who have lung complications. A large proportion of the natives die from pulmonary phthisis, and cases of rapid decline among visitors of this class are numerous. The American physician making a call at Nassau will find the faculty there ready to receive him with urbane cordiality, and he will also find the gentlemen composing it peers of any in the profession.

Further still south are the Windward Islands. Until lately, owing to the extreme difficulty of reaching them, these charming jewels of the sea have been but little known, even as parts of the civilized world, and not at all as sanitaria.

They are of all geological formations—coral, volcanic, calcareous, and primitive; and they thus offer a wide range of choice as to character of scenery. Belonging to six nationalities—England, France, Sweden, Holland, Denmark, and Spain—each island fully imbued with the spirit and pride of fatherland, a trip among them offers an opportunity now rarely afforded of studying the effects of change of climate in modifying hereditary traits of character and in subduing such forms of nervous derangement as are almost peculiar to the country where grew the parent stem. There is but little difference in climate in the different islands of the group, all being alike tropical, only differing as to drainage as they differ in geological formation. But there is a vast difference between them when we come to consider their relative facilities for entertaining visitors. At once we must drop from consideration the three most northern islands—Antigua, Guadaloupe, and Dominica—which have no sort of accommodations for an invalid. But when we arrive at Martinique, all the beauties of a summer paradise greet us, as well as the more prosaic but equally necessary comfort of a most excellent hotel. Surrounding the hotel, in fact covering a good part of the island, are lovely gardens. Were it not for one pest, I would give to Martinique the palm. But there is no rose without a thorn, and in this case the thorn is very sharp and very deadly. A small snake infests the island, whose bite is commonly and rapidly fatal. The "lance de fer"—the iron lance—is almost exactly the size and color of a black lead-pencil, and has as great a fondness for bowers of shade as his victims, with a singularly uncomfortable habit of coiling himself upon chairs and seats. A certain number of natives are killed every year by this venomous pest, and its presence destroys, in a great degree, the keen pleasure which Nature's beauty would otherwise confer. Barbadoes, the colonial capital of British West Indies, is a bustling, busy town, with fine public buildings and excellent shops. It offers, however, no especial attractions to the invalid other than a pleasure call will give, and we may at once go to the end of our route in this direction and disembark at Trinidad. It would be remarkable that this charming island should have been so long neglected as a resort, were it not that there has been, until within the year, no regular steam communication, and that English colonial authorities rather view with coolness the advent of their homes into notoriety. But a better spirit is beginning to prevail, and any visitors who may go there this winter may rest assured of a cordial reception. Dr. James De Wolf, who has been a resident of the island some ten years, and who has gained an enviable reputation, assures me that there is no place in the West Indies where an American invalid may be so soon and so utterly at home. An English community, no interpreters are needed; the winter climate is delicious, with a range of about 14° Fahr., from the coast to the elevated plateau in the background; accommodations are plentiful and good; prices moderate, and society first class. And one very important matter suggests itself to me just here: I have noticed, in more than one resort, that those who are among the earlier visitors get the cream of it. As soon as the natives learn the fact that Americans delight in being humbugged and in paying exorbitant prices for the luxury, they accommodate them in a liberal manner. It takes about five years to get the thing fairly into their heads, it being so totally opposed to their simple ideas of honesty; but once planted, it grows with marvellous rapidity.

But of all the sanitaria for nerve disease in the world, the one which is nearest perfection has been placed by distance at the disposal of our friends of the Pacific slope—the Sandwich Islands. With a choice of climate from tropic to northern temperate,

there is everything to tempt and absolutely nothing to repel the seeker for health and recreation in these isles of the sun.

As to the question, that too is under complete control, it is only necessary to change one's location a few miles to change it, for, on the windward side of the island it rains almost constantly, on the lee side, scarcely ever. I consider the Sandwich Islands the best place in the world for a nerve invalid, and would not qualify this assertion in any way, were they as accessible to our Eastern friends as to Californians.

Looking back, I must give the palm, so far as we are concerned directly, to the West Indies. Either Trinidad or Nassau for a stay, and the steamship trip for a shorter vacation.

Permit me, in closing, to repeat a caution, of which I have before strongly spoken, and this time in the words of a colleague who is excellent authority—Dr. Beard. He says: "Travelling, indeed, is no more a specific than any other medicine in nerve exhaustion. Indiscriminately prescribed, especially without making a differential diagnosis of the case, it is unscientific. It is one of the best remedies; it may be one of the worst remedies; it is a specific for a certain case; it may be precisely the most injurious thing that can be suggested for another case. Almost all medicines are apt to be used indiscriminately. But I doubt whether there is any medicine which is more indiscriminately used than travel, especially in the form of a trip to Europe."

I cannot too forcibly endorse his words, and it is precisely to this end, the proper application of the theories of climate cure, that I have addressed you this evening.

Original Communications.

ACONITE AND OPIUM ANTIDOTAL (?)

By A. CLARK, M.D., LL.D.,

PROFESSOR OF THEORY AND PRACTICE OF MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

At 10 P.M., on a Sunday in April, 1866, Dr. Budd called on me and asked me visit a patient of his who had been taken very sick at his house, where she had called about three hours before. On entering the chamber, I found a lady about thirty years of age, exceedingly restless, moving her arms and legs and body continually; her features pinched and bloodless; her skin cold and clammy; pulseless at the wrist; the heart beating feebly and slowly. She appeared to be *in extremis*. She had been purging and vomiting for more than two hours. A teaspoonful of water could not be retained by the stomach. It was clear that what was to be done must be done quickly. I suggested to Dr. Budd, as there was no hope of help from the stomach, that we try an injection of cold water and brandy into the bowels, in the hope of getting a pulse. This was done immediately, and was rejected as soon as given.

I then asked the patient what she had eaten for dinner, feeling certain that these symptoms were the effects of poison, and not of spontaneous disease. This question brought to Dr. Budd's recollection the fact that he had prescribed tinct. of aconite for her some months before, and he asked her: "Have you taken any of the medicine that I gave you last fall, of which I told you you must never take more than five drops?" "Yes, doctor, I took some of it just as I left home." "How much?" "I don't know; I put the bottle to my mouth and took a little swallow." This was at 7 o'clock, or a little past, and soon after a pretty full 6 o'clock dinner. From this it appears that her mind, in the midst of all this physical disturbance, was clear. Finding that we could not reach the heart by stimulants (subcutaneous injection of alcoholics was not then thought of), we addressed ourselves to the restlessness, and concluded to give a hypodermic injection of fifteen drops of Magendie's solution of morphine.

The effect was little less than magical. In five minutes the restlessness was gone, and in ten minutes she was sleeping quietly. There was no more vomiting or purging; the pulse returned at the wrist. I left Dr. Budd at 10.30, and promised to return at 8 A.M. the next day. At my second visit I was informed that the patient slept well till 6 o'clock in the morning, and then awakened with a renewal of the purging and vomiting and restlessness, when Dr. Budd injected ten drops of the same solution. This was followed by perfect rest and sleep. At 8 A.M. she had nothing to complain of but weakness and soreness of the muscles, from their agitation the night before.

This result was a discovery to us both, for we had never heard that opium was an antidote to aconite, and the morphine was given only in the hope that by its sedative power it would quiet the restlessness.

This case was published in the MEDICAL RECORD, vol. i., p. 169, but it was from notes of a verbal report, and as there are certain errors in that record, it is here reported with corrections.

The publication of Dr. O'Brien's case, similarly treated, in the RECORD of Feb. 8, 1879, without any reference to that case, suggested the reproduction of it.

In this connection I should, perhaps, refer to a case of poisoning by aconite, which shows criminal carelessness on the part of a druggist. It occurred before the one given above, and was treated by emesis and brandy—gastro-enteritis not being a feature of it.

On Sunday morning, after a late breakfast, a gentleman, feeling the need of alvine evacuation, called, on his way to church, upon a druggist, and asked for a teaspoonful of the tincture of rhubarb. It did not taste like rhubarb, but he thought it must be right, and went on. At church, in half an hour, he began to feel very uncomfortable. His sight was obscured. He felt as if his features were moving variously on his face. These feelings, with tingling, increased rather slowly, as the poison was mixed with his food and was absorbed slowly. During the sermon he felt as if he must go home, but, unwilling to make a disturbance, he leaned his head forward on the back of the pew in front of him, and stayed to the end of the service, but comprehended very little what was said or done. As he attempted to rise, he found that he could not stand steadily; but with the aid of friends got home, and sent for his physician, Dr. Linsly. Dr. Linsly saw him with very little delay, and at once suspected he had taken some poison. After prescribing an emetic, he sent for me, and went himself to the druggist. There he discovered that his patient had taken the tincture of aconite—a teaspoonful. Then the druggist made a confession, which nothing but a conscious culpability would, probably, ever have drawn from him: that as the bottle had been drawn down from time to time, alcohol had been added without additional aconite, and he hoped it would not be very dangerous.

I do not remember the symptoms in detail; but the great danger was collapse, such as occurs from an overdose of veratrum viride. His pulse was slow and feeble, with sense of great prostration; feet and hands cold; a slow capillary circulation, with blueness of the nails. He and his friends thought he would surely die, but after the vomiting, to remove any aconite that might be mingled with the still unabsorbed food, we administered brandy freely and resorted to warm friction, and by 10 P.M. he was out of danger.

There was a sequel to this that cannot be without interest to the brethren—an epiphenomenon. Some years after this poisoning, I had some business with one of the city banks, and one of the directors brought me to the president, and was about to introduce me to him, when he exclaimed: "I need no introduction to that man, he and Dr. Linsly saved my life; and, doctor, if you ever want any money, you know where to get it." I have not yet drawn on him beyond the regulation fees.

The first of these cases, in exhibiting the relations of opium and aconite, is so well corroborated by Dr. O'Brien's case, that I offer it to the profession as suggesting probable antidotal relations, with more confidence than I did to the New York Academy of Medicine in 1866.

MALIGNANT DEGENERATION OF A FIBROID TUMOR OF THE UTERUS.

LARGE, FALSE ANEURISM IN THE SUBSTANCE OF THE GROWTH.

DRS. ALBERT N. BLODGETT AND CLIFTON E. WING.

BOSTON, MASSACHUSETTS.

THE following case presented some features which are so uncommon that it is considered worthy of being recorded:

Mrs. E. F——, a native of Massachusetts, was, at the time of her death, in November, 1878, fifty-three years of age. She was married when twenty-four. Had been a widow a number of years. Never was pregnant. Menstruation began at about the age of fourteen, and during all her menstrual life was remarkably regular, recurring each twenty-eighth day with but one exception, when after exposure to cold its appearance was delayed two weeks, and then, for the only time in her life, was accompanied with some pain. The flow usually lasted ten or eleven days; was always profuse, but never enough to cause much prostration or give rise to alarm, and never required treatment. She never had much leucorrhœa. Menstruation apparently ceased the January before her death, but reappeared in small amount in July, and again, for the last time, in August.

At the age of twenty-five (one year after marriage), on attempting to move a heavy piece of furniture, she "felt something give way," as she expressed it, and feeling her abdomen at the seat of the sensation, she for the first time detected the presence of a hard mass of considerable size. This continued to grow gradually larger up to the time of her death. Naturally enough, the lady, when she discovered the enlargement, regarded the strain which she had given herself as its cause, but doubtless the tumor had then existed for a considerable time, and in all probability her muscular effort caused the uterine mass to move, and this gave her the sensation which she experienced.

The tumor did not at this time cause much inconvenience. It was neither painful nor tender, but as it did not disappear, the lady, after a while, took medical advice regarding it, and was told that she had an ovarian tumor. This view of her case she held until a few months before her death, although her family attendant, Dr. Brick, of Worcester, who attended her in her last sickness, has informed me that he regarded the tumor as a uterine fibroid, and supposed that she understood his opinion. She made several changes of residence during her married life, and thus had occasion to employ a number of physicians at different times, but the idea of ovarian tumor seems to have been held by them all, with this one exception. She was a woman of much firmness of character, and when first told that she had an ovarian tumor, took the question of an operation for its removal under consideration (ovariotomy was not then as favorably regarded as now), and, after due deliberation, made up her mind, once and for all, that she would not undergo any operation. This partially explains why, although possessed of ample means, she never consulted a specialist nor any physician expert in such cases. Had she done so, the true nature of her trouble would, on proper examination, have been at once apparent. As it was, the wrong diagnosis caused the case to excite much attention in social circles, for she had a wide acquaintance and many friends, and after it was reported that she had an ovarian tumor, and had decided to have nothing done, it was generally supposed that she would die in a comparatively short time. When, contrary to all expectation, she continued to live, it created much comment, and her case was often cited as proving that the idea held by physicians that ovarian tumors were so fatal, if left to themselves, was erroneous. On several occasions, women with ovarian tumors, who had been advised to submit to ovariotomy, hearing of her case, came from a distance to talk with her before making up their minds. How much harm may have been in this way caused by the mistaken diagnosis cannot, of course, be determined.

In 1861 the lady had a severe attack of peritonitis following a journey by rail to New York, being confined to her room some months, and at several other times, after long drives or active exercise, she had attacks of abdominal tenderness, enough to confine her to the house for a few days, but nothing more serious up to the time of her last illness. In the last years of her life she had several attacks of renal colic, passing at various times a considerable amount of gravel from the bladder. With these exceptions, her sufferings were mainly those arising from the weight and size of the abdominal tumor, which for years made her larger than a woman at the full term of pregnancy; but, notwithstanding the burden which she carried, she led a much more active life than most women, taking into her own hands the charge of her large country place, and always herself driving her pair of ponies. Some time before her last illness she told me, in talking about herself, that she thought she had had quite as little real suffering as the average of women. She was accustomed to eat but little, as "there did not seem to be room for much." She passed water rather frequently, but, strange to say, her bowels were always remarkably regular.

In the spring before her death her friends noticed that she was not seeming as strong as usual, and during the early heated term of that year she was much prostrated, but, on the advent of cooler weather felt better. Still, she did not regain her usual strength. During a friendly visit at her house in the summer, she asked my advice about what she had

considered an umbilical hernia. On examination I found at the navel a large mass of varicose veins, evidently caused by the pressure of the tumor. She also had a bulging at the right inguinal ring, which did not seem to be either intestine or omentum, but simply peritoneum. The tumor at this time presented the hard, rounded surface, and characteristic feel of a uterine fibroid, and appeared to fill the whole lower abdomen, extending above the navel. In the course of the conversation she remarked to me how curious it was that she should have lived so long with such a tumor. I explained to her that there was a great difference in abdominal tumors, that some were of rapid growth, and therefore quickly fatal if left to themselves, citing ovarian tumors as examples, while others were of very slow growth, and but rarely fatal, instancing fibroid tumors of the uterus, such as hers was. She asked if I thought it was a solid tumor of the womb itself, and not connected with the ovaries. I replied, that there could be no reasonable doubt that such was the case. She gave no evidence of being surprised, and I did not then know that she had ever been told that she had an *ovarian* tumor. I learned afterward, that when I left she went to a friend and expressed the greatest astonishment at what I had told her.

Her fatal attack of illness, lasting about three months, came on after she had spent most of a day at a fair, where she was upon her feet much of the time—afterward riding a number of miles to her home. She felt, at the time, that she had done too much. She was soon after taken with abdominal pain and tenderness, and symptoms such as might accompany peritonitis. After a while a large effusion took place into the abdominal cavity. The increased distention gave her much distress, and interfered with respiration, and her physician, Dr. Brick, used an aspirator, and drew off a large quantity of fluid with considerable relief, but she gradually failed, and finally died very quietly, having previously made the request that I should make an examination of her body, in order that if anything should be learned from it, other sufferers might in the future have the benefit of the knowledge thus obtained.

Feeling that the post-mortem examination should be in the hands of a competent pathologist, I requested Dr. Blodgett to make it, and he has written out the following account of what he found:

Autopsy, twenty-one hours post-mortem.—The body is that of a tall, well-nourished person. Rigor mortis not well pronounced. The general appearances give no evidence of prolonged suffering. Limbs generally well developed; face somewhat emaciated. Lower extremities moderately œdematous, particularly below the knees; upper extremities free from œdema. Upon surface of body generally more or less extensive livores, most marked upon dependent surfaces. Two centimetres (¾ inch) to right of umbilicus is a surface of cicatricial skin which extends 7.5 cm. (3¼ in.) toward the pubes, and has a breadth varying from 4 cm. (1½ in.) to 8 cm. (3 in.). The skin is smooth and tense at this part. The cicatrix is not of recent date. Below is a small red spot covered with plasters, where, it is said, paracentesis was performed twenty-four hours before death. Abdomen is enormously distended, presenting almost the figure of a hemisphere, the axis of which would be a line drawn from the ensiform appendix to the symphysis pubis. Through the abdominal parietes a large solid mass can be felt, which occupies the whole of the lower part of the cavity of the abdomen and extends upward to a point half way between the umbilicus and ensiform cartilage, where there is an interval of distinct fluctuation, which is most perceptible in a line across the upper part of the abdomen. Nearer the ensiform appendix, fluctuation is no longer detected, the feeling being as if a soft solid were yielding before the pressure of the fingers. The liver cannot be felt, and percussion is unsatisfactory. The following are the measurements around the body: At the waist, 92.5 cm. (36 in.); at level of umbilicus, 121.5 cm. (47¾ in.); between umbilicus and pubis, 122 cm. (47¾ in.); from umbilicus to ensiform cartilage, 28 cm. (11 in.); from umbilicus to pubis, 30.5 cm. (11¾ in.), from umbilicus to anterior superior spinous process of right ilium, 33.5 cm. (13 in.), from umbilicus to anterior superior spinous process of left ilium, 28.5 cm. (11¼ in.).

Panniculus adiposus thick, and the tissues generally quite moist. Muscular portion of abdominal wall very much attenuated and seemingly atrophied. Parietal peritoneum thickened almost to the density of fascia, feels brawny, and offers considerable resistance to the knife. Upon opening the abdomen a quantity, estimated at 3.5 litres (3¾ qts.), of bloody serum escaped from its cavity. Diaphragm is very much thickened and quite dense and firm in all parts, the muscular portions greatly hypertrophied, the concavity very much exaggerated, reaching on the right side to the third rib, on the left side to the third intercostal space. The internal surface of the peritoneum is covered with numerous hard, firm, rounded prominences, which are either attached by a flat surface to the peritoneum, or are, to a greater or less extent, pediculated and projected into the peritoneal cavity. They are generally of a rosy color and of an uniform consistency. A portion of peritoneum, about 10 cm. (3¾ in.) in diameter, situated midway between the umbilicus and the anterior superior spinous process of the right ilium, is covered with recent shaggy lymph, and at one point upon its surface is an adherent blood coagulum 2 cm. (¾ in.) in diameter and 1 cm. (⅜ in.) in thickness, which apparently followed the operation of paracentesis, and is at present in a state of partial disintegration. Upon the left side is a tuft of about thirty separate filiform processes, which are attached separately to the peritoneum at a point half way between the umbilicus and the axillary line, and extend to the surface of the pelvic growth to be presently described. The seat of attachment of these filamentous adhesions is a surface of about 8 square cm. (3¼ in.). The stomach is not visible, but is found in a position downward and backward from its normal situation in the immediate neighborhood of the spleen. The small bowel occupies a space of about 15 cm. (5¾ in.) by 25 cm. (9¾ in.) surface just below the ensiform appendix, and is much compressed. The surface of the bowel is dotted here and there with small nodular growths, similar to those observed upon the peritoneum. The liver is thickened and elongated, extending far into the left epigastric region, is of somewhat doughy consistency and of grayish, reddish-brown color. Upon being incised, tracings of fatty degeneration of the portal sections of the acini are observable, together with hyperæmia and pigmentation of those portions of the acini surrounding the ultimate branchings of the hepatic vein. The capsule of the liver is at some points thickened, and presents nodules varying in size from a pin's point to that of half a pea, scattered irregularly over its surface, more generally upon the lower aspect of the organ. The spleen presents nothing peculiar.

The whole of the remaining abdominal space is oc-

cupied by an enormous growth consisting of a large central mass surrounded by a number of smaller growths attached to its periphery and projecting in various directions from it. The mass in the centre is of roughly ellipsoidal form, presenting a depression in its posterior aspect, in which a portion of the small intestine is accommodated and entirely concealed from view (until the upper portion of the tumor is raised with the hands), and has a transverse diameter of about 20 cm. (7¾ in.), an antero-posterior diameter of about 17 cm. (6¾ in.), and a height of about 25 cm. (9¾ in.). Upon the right and left sides are excrescences in great number from 5 cm. (2 in.) to 15 cm. (5¾ in.) in diameter. These are most abundant behind and upon the left side, where they completely fill up the left iliac fossa. No trace of bladder, uterus, or rectum can be seen. The inguinal glands of both sides are enlarged and indurated, and the femoral vessels are accompanied in their way to the thigh by a dense funicular mass of tissue with bulbous enlargements scattered along its course.

Owing to extensive adhesions between the tumor and the pelvic organs, particularly on the posterior surface, the whole of the mass was now removed from the body, together with the abdominal blood-vessels, glands, kidneys, spleen, rectum, vagina, bladder, and ovaries, and was placed upon a table where the relations of the parts could be more carefully studied. The bladder was first laid open by an incision extending from the urethra to the fundus. The organ was of moderate size and contained no urine. No sacculations or other signs of vesical disease were observed, excepting a moderate injection of the smaller blood-vessels about the neck. The orifices of both ureters were found at the proper points in the bladder, and a flexible probe passed readily throughout the whole length of each. The vagina is about 13 cm. (5 in.) deep, quite narrow and tense. The finger inserted in it can detect nothing resembling cervix or os, but is arrested by a firm hard wall. Upon laying the vagina open, a linear fissure is discovered in its deepest portion, into which a probe can be passed in a sinuous direction, a distance of about 7 cm. (2¾ in.). The main direction of the canal is forward and toward the left side. Upon cutting the growth so as to expose the canal, this is seen to be the cavity of the uterus, and can be followed to a depth of 15 cm. (5¾ in.). In its course lay an elongated mass of thick gelatinous mucus of greenish-yellow color and tenacious character, and at the deepest portion of the canal are found two or three soft jelly-like mucous polypi which nearly fill its cavity, and are attached by small pedicles to its lining membrane. To the right and left of the uterine cavity the mass swells to a large tumor, upon the surface of which are numerous protuberances of various sizes, from that of a marble to that of an infant's head. The cut surface also shows numerous hard nodules of globular form, which are included in the mass and can be easily separated from the body of the growth. Upon its posterior aspect the tumor gives off many accessory growths, one of which extended deeply into the cul-de-sac of Douglas and pressed firmly upon the perineum between the rectum and vagina. Between the last mentioned portion and the main body of the growth are found, on each side, the ureters, each ureter lying much higher in the pelvis than the new growth, and closely applied to it, but not included in it. After long search the ovaries were found in a position upward, outward, and forward from this region. The left ovary is much encroached upon by a cystic formation of the size of a hen's egg in the broad ligament. The ovary itself seems to be in fairly normal condition. The left Fallopian tube is found and traced for a distance of 12 cm. (4¾ in.), at which point it is lost in the tissues about the tumor. It is pervious until it reaches this point, where no further canal can be discovered. The right ovary is the seat of numerous small cysts containing a clear, glairy fluid. One well-marked relic of menstruation was discovered. The right Fallopian tube cannot be found.

Upon incising the tumor more freely, so as to follow the course of the uterine canal to its extremity, the median orifices of both Fallopian tubes are found, and both are pervious as far as the point where they emerge from the tumor, at which place there is atresia of both tubes for the space of 0.5 cm. (¼ in.); beyond this point both tubes are again pervious. The left tube measures 20 cm. (7¾ in.), the right 28 cm. (11 in.) from the surface of the tumor to the fimbriated extremity. Several large calcareous masses are found in various parts of the tumor, some of which seem to have resulted from extensive central calcification of certain nodules of the new growth, while in other parts the hard masses are made up of numerous small distinct nuclei of separate calcification. In many parts of the tumor, the true uterine muscular tissue is still found, while in other parts it cannot be detected. A large soft nodule, 15 cm. (5¾ in.) in diameter, springs from the right side of the tumor at its posterior part, and upon being incised proved to be a *false aneurism* of 13 cm. (5¼ in.) diameter, the wall of which is composed of uterine muscular tissue, and which is filled with blood. That portion of the clot which is in apposition with the wall of the sac, presents the appearance of having been effused at some considerable period previous to the death of the patient, and is partially organized and quite adherent to the wall of the sac. The central portion of the mass is occupied by a large soft clot of recent blood. Large vessels can be traced in the wall of the sac, but no communication can be discovered with the mass in the centre. Upon carefully turning out the clot from the median half of the sac, a large calcareous mass is found at its base, which protrudes to a moderate extent into the cavity of the sac. Upon one side of this mass is a true aneurism of one of the larger vessels, of flattened shape, 3 cm. (1¼ in.) long, 1 cm. (⅜ in.) broad, and 0.5 cm. (¼ in.) deep. From the aneurism, blood-vessels pass in various directions, and two are discovered which open by torn and ragged extremities into the large sac before mentioned. A probe passed into either of these vessels emerges in the central clot of the large sac. This was afterward shown to the late Dr. Jackson, who pronounced it a remarkably exceptional occurrence, and said that in his large experience he had never observed a similar instance in connection with a fibroid tumor.

The rectum is flattened and closely applied to the pathological growth, to which it is firmly bound by connective-tissue adhesions. At the situation of the sigmoid flexure it is forced into the shape of the letter U; its calibre is much diminished, and in some parts almost obliterated. Above this portion the bowel is moderately distended with fæces, and seems to be in normal condition. The lumbar glands are bound firmly together about the cœliac axis, and are adherent to the posterior aspect of the tumor. The blood-vessels are not noticeably affected, and are pervious. The blood-supply to the pathological growth is mainly from branches of the internal iliac arteries, though other sources of nutrition may have existed. The kidneys were found in their normal relations to the aorta, and were carefully separated, leaving only

the ureters attached. These were followed downward and outward around the sides of the morbid growth, where they lay in intimate relations with it, but are not included in its structure. Both ureters are pervious, and show no signs of disturbance of function from the proximity of the diseased growth.

Microscopical examination of different portions of the foreign growth reveal a varying structure. The original tumor, in which the tissues of the uterus are found imbedded, is formed of dense connective tissue. Bundles of this tissue, with spindle-shaped cells, run in different directions, interlacing so as to form a close, firm structure, presenting the well-known appearances of an ordinary fibroid of the uterus. Some of the newer portions situated upon the periphery of the original growth possess the same structure, but others are composed of connective-tissue cells of varying shape and of large size, with large nuclei, provided with only a scanty intercellular substance, from which they easily separate, and float about in the field of the microscope, thus presenting a character not belonging to the structure of fibroid, but peculiar to sarcomatous growths. In many of the nodules projecting from all parts of the original fibroid the histological structure is so decidedly sarcomatous, that, judging from these portions alone, no one would suspect fibroma. The lymphatic glands of the lumbar plexus are enlarged and present the appearances of sarcomatous growth above described. The bronchial glands are affected in a peculiar manner: certain of them present only the ordinary structure and size of these glands, and are pigmented in the usual manner. Others are found in the immediate vicinity which are much enlarged, sometimes being double the size of their neighbors, and these upon section show the original pigmented gland in the centre, surrounded by a layer of varying thickness of a white color, which presents, under the microscope, the same general appearances as the sarcomatous growths in the pelvis, and are evidently of metastatic origin. Scattered through the pulmonary structure, more generally in the lower lobes, are numerous nodules of a similar structure. These are firm, white or whitish-yellow, and vary in size from that of a pin's head to that of half a pea. Throughout the whole abdomen are countless pendulous masses attached to the viscera, to the omentum, to the ligaments of the liver, to the surface of the bowel in its course, and to the whole upper part of the parietal peritoneum. These growths vary in size from that of a pea to that of a grape, are of somewhat irregular shape, of whitish-gray color, and prove to be of still another histological structure. They are made up of round cells, and surrounded by a capsular layer of varying density, and are good examples of *granulation tissue*, such as is found in the indurated base of chronic ulcers, and is also the medium of new formation in the healing of wounds. These excrescences seem to have resulted, not from any infection from the tumor, but from the long-continued irritation caused by its presence, and resemble the papillary growths sometimes seen in other parts of the body as the result of chronic inflammatory action. The kidneys were apparently normal, as were the remaining abdominal organs. The heart was not noticeably diseased. A considerable amount of fat was deposited on and about it, but not more than the amount corresponding to the corpulency of the individual. The valves are all in a healthy condition. The head was not examined.

In these days of operative interference the full history of such a case, left to run its natural course, is interesting, particularly so in this instance, on account of the rare conditions revealed by the autopsy.

In former times, uterine fibroids were pretty generally looked upon as of a malignant nature and confounded with "cancer," especially when they grew to very large size. More lately, since their benign character has been understood, many distinguished authorities have held to the opinion that they were never the seat of primary malignant degeneration, and there has been considerable discussion upon this point. At present, although the possibility of such degeneration is generally accepted, its rareness is denied by no one. There are but few undoubted cases on record. From the post-mortem appearances in this case there seemed but little doubt that the primary change began in the uterine mass, the changes found elsewhere being secondary in character.

The finding of the false aneurism in such a growth was entirely unexpected. That it should have attained such a size when its walls were formed of firm, dense, uterine tissue, is remarkable, and only to be explained by remembering that the principle of hydraulics utilized in the hydraulic press must have come into play here up to the time of the coagulation of the effused blood.

On abdominal palpation after death, I was surprised to feel the large mass formed by the aneurism, supposing at the time that it was an irregularity of the fibroid, and wondering why, in feeling of the tumor in my examination some months before, I had not at once detected it, as then there was apparently no water in the abdominal cavity, and the surface of the growth could be plainly felt. On explaining to an intimate friend of the deceased, who was with her constantly during her sickness, what was found at the autopsy, she at once asked if the aneurism would not account for the fact that the pain was always worse on the right side, and told me that the patient, during her sickness, often spoke of a strange "swashing" sensation at that point, saying that that was the only word which seemed to at all express the feeling. It therefore seems likely that the aneurism formed, and became filled with the clots found in it, during her last illness.

It is also worthy of notice that, with such a large, irregular fibroid, the woman never suffered with dysmenorrhœa; the menses were regular; metrorrhagia never occurred. Notwithstanding the encroachment upon the calibre of the rectum, there was no constipation, and in spite of their position between masses of the growth, the ureters were not obstructed and the kidneys remained healthy.

It is interesting to consider what might have been the result had an attempt been made to remove the uterine mass by the operation of hysterotomy, made popular of late years by the publication of the treatise of M. Péan, of Paris. The fact that with the exception of the tuft noted by Dr. Blodgett in his autopsy record, and which might have been easily separated, there were no adhesions *above the pelvis*, would very likely have induced the operator to go so far in attempting to separate those found *in the pelvis*, that before he was convinced the operation was not feasible, he would, perhaps, have inflicted an amount of damage incompatible with the recovery of the patient.

Again, supposing that the operator had succeeded in separating the pelvic adhesions, that portion of the growth which intruded upon Douglas' cul-de-sac lay so much lower in the pelvis than did the ureters, and the latter were in such intimate relation with the mass, that one or both of them might easily have been injured in the removal of the tumor.

This latter danger is not an imaginary one. I have myself seen the accident happen at the hands of a well-known operator. The case is reported in the *American Journal of Obstetrics* for August, 1876, but no mention is made of the autopsy or this fact disclosed by it. In this case the tumor weighed fifty pounds, and was of such rapid growth that it was at first thought to be ovarian. As in the case we report, there had been little or no leucorrhœa, no dysmenorrhœa, and, up to its cessation, one year before, perfect regularity of the menstrual function. The flow, however, had usually lasted but three days, and been scanty during that time. The patient's sufferings arose simply from the weight of the tumor. She was able to walk about, had a good appetite, and good digestion.

At the operation there were found pretty general adhesions at the upper part of the growth, which were easily separated. Luckily, there were no firm adhesions in the pelvis. Finally, the mass having been raised by assistants, the pedicle, consisting of the vagina and adjacent tissues, was ligated and cut, and the tumor removed. The patient, after rallying from the operation, soon began to show symptoms of internal hemorrhage, and next day the abdomen was again opened, cleansed of much effused blood, and a vessel, which had been torn in sep rating adhesions, was found bleeding and tied. The patient being very low, transfusion was attempted without result. The next day transfusion was again done, but with no perceptible effect, and the patient died.

At the autopsy considerable effused blood was found in the abdominal cavity, probably having come from other vessels torn in separating adhesions. A loop of the left ureter was found included in the ligature which had been tied about the upper part of the vagina. The ureter above the part was very much distended, and the corresponding kidney in a state of acute disintegration.

The operator, Dr. Thomas, in the last edition of his well-known text-book, mentions the case twice in the chapter on uterine fibroids. At one place, in speaking of the size to which such tumors sometimes grow, he simply states, without further particulars, the fact that he has "removed one with uterus and both ovaries" weighing fifty pounds. Twenty pages further along, a foot-note to a table of statistics in which the case is tabulated as fatal, gives the same information. There is no reference to the injury to the ureter, nor is the liability to this accident included in his mention of the dangers of removal of fibroid uteri by gastrotomy. Thus the only particularly instructive point about his case is not brought out. Curiously enough, the chapter closes with the sound remark, "gastrotomy should be performed only when life is in jeopardy."

Sickness During the Zulu War.—The sickness amongst the troops in Zululand during the late war was very great. The polluted water, the hot days and cold nights, and the exposure, were the chief causes. The most frequent diseases were fevers, diarrhœas, and pulmonary complaints. The most frequent fever was the simple continued. Enteric fever, when it occurred, was very fatal. Remittent fevers were not unfrequent. The dysenteries were produced by exposure, by neglect of diarrhœas, and in some cases by the cutting off of beers and spirits from those long accustomed to their use.—*Brit. Med. Journal.*

A NEW METHOD OF RECTAL ALIMENTATION.

By F. E. STEWART, Ph.G., M.D.,

NEW YORK.

In my article published in *New Remedies*, Vol. VIII., No. 12, entitled "A New Method of Rectal Medication," calling attention to rectal (gelatin) capsules, and the oleates of the alkaloids per rectum, the absorbent power of the intestinal mucous membrane was quite fully discussed. Advantage has long been taken of this power for the purpose of alimentation as well as medication, and although the rectum as an absorbing surface is inferior to the stomach, and for obvious reasons not fitted to take its place as the organ of digestion, still this power of taking up food is of great importance when for any cause the stomach is incapable of performing its function.

For alimentation the rectum can be resorted to as an auxiliary organ to the stomach, or it can be used for a time as a substitute for it, in supplying the system with food. It is to the former we wish to call attention, and to desiccated defibrinated blood as an agent especially adapted for rectal alimentation.

But, before proceeding, an explanation is necessary. For more than a year past the writer has been experimenting with defibrinated blood as an aliment in disease. The subject was suggested by the popular idea that warm, fresh, defibrinated blood, quaffed at the butcher's shambles, is remedial in consumption and other wasting diseases. Investigation of this singular practice certainly does show that many cases are remarkably benefited by it. This, of course, can be accounted for in many ways without referring it to the blood—the healthy outdoor exercise of a walk, or ride, to the abattoir, or diversion of the mind by so novel a remedy—but it cannot be denied that defibrinated blood is rich in the elements of nutrition, and the resulting benefit of its use is out of proportion to the novelty of the medicine, or healthy exercise in obtaining it.

To utilize, therefore, what appeared to be a valuable product, a process was devised for drying it, quickly to prevent decomposition, and at a low heat. After shipping a large invoice of this desiccated blood to Detroit, to be used as an aliment, I discovered that Dr. A. H. Smith, physician to St. Luke's Hospital, New York City, was also at work with defibrinated blood, and had proved its therapeutic worth in more than sixty cases. At my request, Dr. Smith substituted the dried article at St. Luke's, where it is now on trial and appears to be of equal worth to the blood before preparation.

This, then, will explain the reason why desiccated blood is brought to the notice of the profession as a new article for rectal alimentation.

There are three ways by which blood can be introduced into the system—per orem, by transfusion, and per rectum. The last named seems, for many reasons, the least objectionable. Naturally enough, drinking blood is disgusting to patients. Transfusion, even in the most careful hands, is not devoid of danger. But injection per rectum is an easy and safe operation, which can be frequently repeated without risk of injury.

Blood per rectum has also the advantage possessed by transfusion of not being subject to the changes incident to the process of digestion.

Various articles are used for rectal alimentation—milk, albumen, and lately albuminose has been recommended. To be of any use to the system they must be taken into the circulation, converted into

blood, or else substituted for it. Blood is the product of digestion, and it is supposed that before food can be converted into blood, the saliva, gastric, pancreatic, and intestinal juices and bile must perform their action, absorption must take place and, finally, that wonderful, vital constructive process by which the corpuscles are made, and the blood is fitted to perform its part in nutrition. If this be all true, blood cannot be manufactured from these articles when injected into the rectum, and their beneficial effect must be accounted for in some other way. It would seem, therefore, that blood itself, for rectal alimentation, if absorbed, would be more suitable to meet the wants of the system.

Blood is the food and air of the tissues. As it is the province of the vegetable world to convert the elements of surrounding nature into organic forms fitted for food, so it is the province of digestion to convert food into blood to feed the vital organs. Blood is therefore called the *vital fluid or the life*, and its presence in the vital organs is indispensable to their function. Only a momentary arrest from the brain results in syncope, or fainting away, and any organ deprived of it soon loses functional activity. Supplies for the growth and repair of the whole body are in the blood. Blood is but the body in a liquid state. Being, therefore, perfectly adapted to build and construct tissues, and indispensable to life, its administration would seem to be indicated when tissues are wasted and life is threatened by disease.

Like other vital organs, the nerves depend directly on the blood for their functional activity, and deprivation results in morbid phenomena. Close physiological relations exist between the red globules of the blood and the healthy life of the nerves. This relation is probably between the hemoglobine—the red coloring matter of the blood, which forms the principal substance of which the red globules are composed (about 25 to 30 per cent. of their weight, or 86 per cent. of their solid ingredients)—and the nerves. A morbid diminution of the red globules is designated anæmia. As the action of every organ in the body depends upon the nerves, it naturally follows that if they be impaired, there is a general deficiency of functional energy. All the vital functions are languidly performed. The action of the heart is feeble, and easily disturbed. Mental energy, strength of will, and purpose, are diminished. Neither can the action of impaired nerves on the secretory organs manufacture healthy digestive fluids for the preparation of food to be converted into healthy blood, so necessary for nerve supply. Then, too, the brain sympathizes in this condition, and the mind, becoming affected, in turn reacts on the nerves to increase the disorder.

Nutrition is directly under nerve control. Every secreting cell, every absorbing villi, the inherent power of each tissue to select from the blood appropriate matter for its repair, even the muscles for respiration, are supplied by artery and vein, with nerve to guide their action, for the purpose of furnishing them with blood, to be used for building new tissue, and to impart nerve-force to repair that lost in the exercise of their functions.

Desiccated blood is therefore suggested for rectal alimentation, when the life-powers are threatened by asthenia, due either to loss of blood, loss of nerve-power, or to both. It is indicated in all cases where, for any reason, digestion is impaired, in cachectic states from special constitutional poisons, and in all cases when impaired blood, nerves, or digestion give rise to the anæmic condition with its resulting general debility, hypochondriasis, or other functional disorder.

It is hardly reasonable to infer, and clinical experience does not justify us in believing, that blood is absorbed from the rectum without a breaking down of the corpuscles, but there are good reasons to suppose that it enters the system without marked chemical change, and it has been satisfactorily proved by Dr. Smith, and other scientific physicians, that its use is remarkably beneficial to patients. How much this is due to the hemoglobine and its action on the nerves, remains an interesting matter to determine.

Blood for rectal alimentation must be from healthy animals. Inflammatory blood from diseased cattle will not do, or blood from animals fatigued from long journeys. None but powerful, vigorous bullocks, fed and rested until the heart's action regains its normal tone, should be selected for this purpose.

Killing must be done in a manner to secure healthy blood. This can be accomplished only by bleeding to death. Striking on the head, or in any other way causing death from apnœa, prevents a proper arterialization of the blood. Blood from animals killed in this manner, or the inflammatory blood from diseased cattle, is unfit for use in the arts, and therefore must be too imperfect for employment in therapeutics.

Great care also must be taken in the preparation, due attention being paid to all chemical and vital phenomena. Long exposure to the air in a fluid condition, or too high heat, not only decomposes, but devitalizes it, and if the heat be raised to 160° F., coagulates the albumen. No heat above 110° F. should be used in the drying of blood, and the process should be as instantaneous as possible, and without agitation.

Desiccated blood, as thus prepared, is completely and readily soluble in water at all temperatures below 160° F., and contains all the elements of blood, except water and fibrin. The loss of the latter does not seem to impair its nutritive value, being but a very small proportion of the nitrogenous constituents of the blood.

A little more than a drachm of the dried article is necessary to represent a fluid ounce of blood of ordinary specific gravity, but it is sufficient to remember, in using, to employ a drachm to the ounce of water. To dissolve, it should be thrown into water, and allowed to stand until the albumen becomes perfectly soft, to prevent sticking to stirring rod or dish. Gentle agitation will then convert it into a perfectly homogeneous fluid, closely resembling fresh blood. It is a very difficult matter to dissolve dried blood by pouring water upon it, for it immediately adheres together in lumps, and sticks to everything brought into contact with it.

From four to six drachms of the powder daily, or more, is the dose, which may be given at once, at bedtime, or in divided portions during the day, as circumstances seem to require.

If a greater amount than can be absorbed be injected at once, and decomposition result therefrom, it is advised to wash out the rectum with tepid water before continuing the medication.

For further information on this subject, the reader is referred to Dr. Smith's paper, read before the New York Academy of Medicine, to his paper before the Therapeutical Society, and to the minutes of these respective societies for their action in the matter.

The MEDICAL RECORD and *New York Journal* have reported on these papers, and are also referred to as containing very nearly as full information.

Progress of Medical Science.

Clinical Studies on the Hemorrhages of Whooping-Cough.—At a recent meeting of the *Académie de Médecine*, M. Henri Roger read a very interesting paper with the above title. He considered successively *epistaxis*, which is produced in a direct manner by the convulsive shocks of the cough, and which only rarely becomes dangerous from its abundance and frequent repetition—in which case it is complicated by an alteration of the blood; *subconjunctival* or *palpebral ecchymoses*, which also depend on the cough, and which sometimes serve to differentiate the cough of pertussis from that of ordinary bronchitis; *otorrhagia*, *purpura*, and certain *visceral hemorrhages*. He then took up the subject of *hæmoptysis*, and demonstrated by numerous observations that this form of hemorrhage, as well as hæmatemesis, is exceedingly rare in children. In almost all cases the supposed hæmoptysis of pertussis is really a pseudo-hæmoptysis—the blood being furnished by the nose, mouth, or pharynx, but it may almost be said never by the pulmonary organs. Hemorrhage from the mouth comes next to epistaxis in point of frequency. The blood may come from the gums, or from a solution of continuity in the mucous membrane of the cheeks or tongue; sometimes it comes from the pharynx or the nasal fossæ—the buccal hemorrhage in this last case being preceded and accompanied by epistaxis. Occasionally the blood expectorated has a complex origin, being derived simultaneously from the nasal and buccal cavities. Sometimes, at the end of a paroxysm, the child expectorates a bloody foam, which is produced by the intimate mixture of the blood with bronchial mucus that has become aërated by the repeated concussions, and this expectoration of bloody froth is often wrongly regarded as a sign of tuberculosis, an error which can readily be recognized by an examination of the mouth. M. Roger claims, moreover, that pulmonary hemorrhage of tubercular origin is excessively rare in childhood; he has only observed it after the tenth year, and even then only in exceptional cases. With regard to early infancy, it may be said to be *exempt from hæmoptysis*—pulmonary hemorrhage being never at this age the initial sign of phthisis. M. Roger does not claim that true hæmoptysis absolutely never occurs, but merely that it is very rare; on this point he differs from Trousseau, who said that it is pretty often met with.

Pseudo-hæmatemesis is also observed in pertussis. When a child suffering from this affection seems to vomit blood, a careful examination of the nasal fossæ will always reveal the fact that an epistaxis has existed. The blood has flowed through the posterior nares and into the stomach, often without attracting attention, and it may accumulate there in considerable quantities. If it be expelled immediately, the flow from the anterior or posterior nares will still be visible; if it be retained for a time until the epistaxis has ceased, some drops of blood or clots in the nose will suffice to indicate the source of the hemorrhage. It may be mentioned here that true hæmatemesis, like hæmoptysis, is entirely exceptional in childhood, and is scarcely ever met with except in some very rare cases of purpura.—*Gazette Médicale de Paris*, Sept. 20, 1879.

Albuminuria without Disease of the Kidneys.—In three anæmic, but otherwise healthy men, Edlefsen observed transitory albuminuria after severe bodily exertion. Leube has met with a relatively large number of such cases in soldiers, and he has sought to account for the albuminuria by the theory that muscular exertion causes an increased infiltration of albumen into the glomeruli. Edlefsen, however, does not accept this theory, but offers the following explanation of the phenomenon: In healthy men, according to Ranke, the muscles, when in active exertion, contain an increased quantity of blood, while at the same time the organs that are at rest contain a correspondingly smaller supply of blood. This difference in the blood-supply of the temporarily inactive organs must be still greater in anæmic persons, since the weakened muscular tissue of the heart is unable, in response to the increased demands made on it during bodily exertion, to force a sufficient supply of blood into the aorta, the result being that the internal organs receive still less blood than they would in a state of health; moreover, the blood, for the same reason, accumulates in the pulmonary and venous systems. Now, Runeberg found, after numerous experiments, that in the filtration of albuminous solutions through animal membrane, contrary to the formerly received opinion, the readiness with which the albumen passes into the filtrate increases in an inverse ratio to the diminution of the pressure exerted, or, when the filtration takes place into a fluid surrounding the filter, in a direct ratio to the increase of the pressure exerted from below, and from the sides against the filtering membrane. Applying these facts to the phenomenon in question, Edlefsen argues that albumen, which cannot pass through the vascular membrane of the glomeruli Malpighii under the normal condition of pressure, can pass through it when the pressure is diminished by bodily exertion, and more especially when the person is anæmic, because then the simultaneously overfilled veins increase by pressure on the urinary tubules and the fluid contained in them, the counter-pressure on the vascular membrane of the glomeruli, and thereby lessen the difference between the direct and the counter-pressure on the membrane.—*Berliner klin. Wochen.*, Sept. 22, 1879.

Simple Treatment vs. Antiseptic.—Dr. S. W. Gross requires strict cleanliness of instruments and dressings, but makes no use of carbolic acid. The instruments are not placed in antiseptic solution before the operation, nor is any attempt made to operate under the spray. In spite of this he claims as good results as the most perfect Listerization could produce.—*The Medical and Surgical Reporter*, Nov. 15, 1879.

Annual Meeting of the Training-School for Nurses.—The seventh annual meeting of the New York Training-School for Nurses was recently held at the Nurses' Home, opposite Bellevue Hospital. Mr. Wm. E. Dodge presided, and read the annual report of the managers. It showed that ninety nurses in all had been graduated since the establishment of the school in 1873. All the female patients in Bellevue Hospital, two male wards, the Sturges Pavilion, and the Lying-in Hospital, are nursed by pupils of the school. It now has every evidence of great prosperity.

After the reading of the report, Prof. Wm. M. Polk made a few remarks. Rev. Dr. Vincent then presented diplomas to a graduating class of twenty-three.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 3, 1880.

THE DOCTORS' BILLS.

In footing up the accounts of the old year, the practitioner of medicine learns many lessons from humanity. Fortunate is he if, in the estimate of the amount from bills receivable, he is able to realize the payment of anything like what he had been led to expect at the time of rendering the services. Willingness to pay the doctor is too often narrowed to that short period when the grateful patient can focus his pocket-book through his tears. In looking over the items in his day-book the physician can now recollect when was the favorable opportunity for receiving the fee, and how he missed it. Then any sum would not have been too great to pay him for the relief of pain or the actual saving of life. The doctor smiles now as he thinks of the pretensions of his grateful patient, and verifies afresh the forgetfulness of impetuous gratitude. The man who would then have no other attendant, now apparently feels so many obligations to the one who once saved his life, and whom now he owes, that he does not wish to trouble him any more. His readiness to pay at the time he thought, his wife was dying, or when his Harry was snatched from the jaws of death, has vanished into the shadowy uncertainties of a more convenient season, and he now comforts his conscience that, after all, it was nothing more than an ordinary service, and the doctor can wait for his money. It would not be proper, of course, for the doctor to consult his own convenience in answering the call. Suffering humanity demands immediate attendance. Sleep, meals, family obligations, and social recreation must be sacrificed to it, and the attendant must be content if, in the majority of cases he can earn for himself the reputation of being obliging to his patrons and attentive to his business.

When we descend from the lofty conceptions of professional obligations to the more material element of pecuniary remuneration, our poetry degenerates into the common prose of butcher and grocer bills. We are speaking now of the patients who ought to pay, but who do not; also, of men who believe, if they ever intend to remunerate the doctor at all, that his bill must be the last on their list. In one sense it is flattering to imagine that the medical profession is above the want of money, that it performs the duties of its high mission without being subject to the temptations of ordinary mortals. Viewed from other standpoints, the outlook is not encouraging to one who feels that he ought to live by his profession and be decently compensated for his work.

To return to the relations of gushing thankfulness to actual pay—what a sorry lesson does the man of experience learn in studying them! We almost imagine him to be cold hearted when, unmoved, he listens to the tearful acknowledgments of Jones, when Johnny is out of danger; to the outpouring of generous sentiments by Mrs. Black, when Cæsar Black, Esq., is again restored to health. Nor must the younger practitioner believe his older brother to be unthinking or profane if, when long after the bill is due, he hears him humming Rabelais' couplet concerning the sick devil who thought of becoming a monk.

When the young man's ledger is four or five years old, and he refreshes his memory concerning promises of patients unfulfilled, he too will become a trifle suspicious and learn to sympathize with his seniors. It has often been said, even by those who are disposed to pay every one else promptly, that physicians should never be in a hurry for their money. Really it would seem that the services of the doctor are placed even below those of the plumber in regard to the time and willingness for payment. On the other hand, it is well known that in the majority of cases the longer the bill is deferred after the thankful, appreciative, or tearful period, the less the chances are of getting it at all. And the physicians themselves are in a great measure to blame for this. They have educated the people to be tardy in their payments by showing an indifference as to the time when the accounts should be rendered. What they look upon as a small matter with themselves, is being considered as such by their patrons.

Then, again, so much medical service is rendered gratuitously, that it is hard to convince some people that it is worth anything. The system of "dead-heading" for clinical, dispensary, and hospital material has developed itself into a science which is now even better understood by the patient than by the doctor. When so much of this is going on, the patient with an elastic conscience can easily excuse himself from any obligation, pecuniary or otherwise, to his physician. The latter may consequently book what he pleases and collect what he can. It is fair to suppose, taking all the chances into account, that fully one-third of his visits will be found to have been made for naught; and if he collects the remainder of what is due him

within a reasonable period, he will be more fortunate than the majority of his brethren who are now settling up the accounts of the year.

THE CATTLE PLAGUE.

There are well-founded reports to the effect that the cattle plague is extending itself into Westchester County, and infecting a number of animals. In this city and in adjacent districts on Long Island, where the disease has been almost epidemic for the past year or two, very active measures have been resorted to by the State Commission to arrest its progress. Not only have efforts in this direction been successful, but the malady here has been virtually stamped out. The latter has been accomplished by killing the infected animals, it having been proven that there is no cure for the disease, and that it is highly infectious among horned cattle. The affection, as it appears in Westchester, is of a comparatively mild type, but the ultimate damages to the cattle in making them unfit for milking, unsuitable for food, and unsalable for breeding purposes, are virtually the same.

Pathologists have shown that the disease is peculiar, particularly in its pathological lesions. It may be considered, in a general way, as pneumonia complicated with pleurisy, but with the addition that portions of the inflamed lung become necrosed and actually separate themselves. This latter phenomenon is supposed to be due to the anatomical arrangement of the pleura, which has some peculiarities not possessed by the same membrane in the human subject. The lobules are not only very loosely connected with each other, but extending between them are folds of the serous membrane. The latter become inflamed, increase very much in thickness, and strangulate the lobules which they surround. The sloughing portion then becomes more or less globular in shape, and discolored, presenting a gross appearance, very much like a ball of manure. In the substance of this mass bronchial tubes and other elements of pulmonary tissue are found.

The disease is quite insidious in its approach, but when developed is easily diagnosticated, all the usual physical signs of pneumonia being present. The animal has a high temperature, quite frequent pulse, difficult breathing, and stands with legs well apart, as if such a position enabled him to breathe freer. The duration is generally many months, the symptoms gradually developing into those of cheesy pneumonia, and the animal dying very much emaciated. During the past winter the disease has been very thoroughly studied by several pathologists, and the conclusions reached regarding the character of the lesions, the general history of the disease, and the uselessness of treatment with the view of curing the disease, are founded on accurate scientific data.

NURSING AT GUY'S HOSPITAL.

It is intimated by the *Medical Press and Circular* that the foundations of that venerable institution, Guy's Hospital, are being shaken to the bottom through the recent conduct of its head-nurse. This head-nurse is a new acquisition, one who came from Leicester Hospital, clad in unassuming gray and endorsed by the best testimonials. Beneath the subdued apparel, however, and behind the spacious array of glowing testimonials, was concealed a spirit of arrogance and grinding tyranny, which have deeply aroused the subordinate nurses, have nearly paralyzed the executive management of the hospital, and have quite shocked our esteemed contemporary the *Medical Press and Circular*. The atrocious—one might almost say immoral—measures which this bad woman has inaugurated have been the requiring every nurse to dress in gray instead of black; requiring the nurses to change from one ward to another when directed by the matron, with certain other minor regulations in regard to salary and length of service. Many nurses have left on account of the hardships thus forced upon them, and the *Press* has taken up their cause.

The fact that the matron simply changed the uniform from black to gray is of itself hardly an indication that she may be so great a monster as is supposed; while the change of nurses from one ward to another is a practice to be commended in all hospitals. In this country, where we have the best trained nurses, it is a very satisfactory one. Many of the nurses, it is stated, have been in the same wards for fourteen or more years. Now, it may be safely stated that no female nurse can stay in one hospital ward for fourteen years without becoming something of a "Gamp." We think it likely that "Gampism" is quite as much to blame as the new matron in the present trouble at Guy's. We have great confidence, therefore, that the hospital will get safely out of the very tempestuous condition into which the novelty of an attempt at discipline seems to have thrown it.

SCHOOL HYGIENE.

A writer in a recent issue of the *Tribune* calls attention to the advantage of building school edifices in independent sections, so that, for instance, each room shall be complete in itself regarding its appointments of light, heat, and ventilation. The public schools—and, unfortunately, these are to be considered as the types of what is now called perfect school architecture—are constructed on the principle of a large auditorium divided into smaller rooms by temporary or permanent partitions, each being an inseparable part of the whole. Hence it often happens that, where one source of heat is relied upon, the temperature is so uneven as to make few comfort-

able. The scholars near the source of heat suffer on account of its intensity, and the windows are opened in self-defence, while those farthest off are suffering with the cold. He very justly urges in this connection that each class-room should have an independent supply, and should depend for ventilation upon other means than those afforded by open doors. The recent discussions on the unhealthfulness of our public schools has been productive of much good, and has brought about many improvements in heating and ventilation, but that much more is needed to make their habitation tolerable can easily be proven by any one who will take the time or trouble to inspect the buildings. We are aware that this will be considered as the old story, but our only regret is that there is still a necessity for repeating it.

HOSPITAL SUNDAY.

CERTAINLY those interested in the care of the sick poor, and the prosperity of our hospitals, have good reasons to be satisfied with the results of the contributions for hospital Saturday and Sunday, made last week. These were the first occasions of their kind in this country, and, as initiatory movements for general charity toward a most deserving class of sufferers, they were as successful as could have been expected. What has been done thus far is but the beginning of what will hereafter be accomplished in the way of donations to these worthy institutions. Americans are proverbially a generous people, and they need only to be assured that their alms are worthily bestowed to make any benevolent project successful. The press of this city took hold of the matter with earnestness, and by the free publication of notices, and by telling editorial articles, anticipated public opinion, endorsed the plan of contributions from the start, and prepared the people to give wisely and well.

No one was denied the opportunity of contributing. The receiving-boxes were placed along the routes of public travel, the yellow flag reminding all of the day and the occasion, and many were the silver bits which were dropped in. The churches were alive to the spirit of the day, and did their utmost to demonstrate a Samaritanism which was of the truest kind, because it was the most practical. Every giver, and they were very many, was made to feel that his gifts found the right channel, and that he was doing a work in keeping with that of Him who was always kind to the sick and the poor. As a matter of history, then, hospital Saturday and hospital Sunday are established institutions in this city. We can recommend other cities containing hospitals to go and "do likewise."

MEDICAL BARONETS.—London has five medical baronets: Sir W. Gull, Sir W. Jenner, Sir J. Paget, Sir T. Watson, and Sir G. Burroughs. Ireland is now clamoring for some.

Reviews and Notices of Books.

HOLDEN'S MANUAL OF THE DISSECTION OF THE HUMAN BODY. Edited by LUTHER HOLDEN, President of the Royal College of Surgeons of Ireland, etc., and JOHN LANGTON, F.R.C.S. Fourth edition. Philadelphia: Lindsay & Blakiston. 1879.

THE present edition comes to us thoroughly revised, and with some additions to the anatomy of the nervous system and the special senses. The arrangement of the work is of great practical utility to the student of anatomy, as it takes him by easy stages of dissection through the most complex constructions of the human body. By this means the surgical relations of parts are firmly impressed upon the mind, and the body is studied as a complex structure. The diagrammatic representations of distribution of arteries and nerves are of great service, impressing facts at a glance which could not be obtained from text descriptions, however lucid. Such associations, by means of illustrations, are everything compared with abstract memorizing, and need but to be mentioned to be appreciated.

The general character of this work is so well established, that it is unnecessary to say more than that the present edition is fully up to present requirements. The publishers have imported the English sheets, and of course present the work in a style which is simply matchless as regards clearness of print and character of illustration.

GUIDE TO THE EXAMINATION OF URINE; with Special Reference to the Diseases of the Urinary Apparatus. By PROF. K. B. HOFFMAN and DR R. ULTZMANN. From the Second Edition. Translated by T. BARTON BRUNE, A.M., M.D., Maryland University Hospital, and H. HOLBROOK CURTIS, Ph.B. New York: D. Appleton & Co. 1879.

THIS book is very neatly published by the Appletons, and is the same material that has already received a favorable notice in this journal for December 6, 1879, and published by Peter G. Thomson, of Cincinnati. The general appearance of the volume offered by the New York house is superior to that presented by the publishers in Cincinnati.

NOTES ON NORMAL HISTOLOGY. By T. MITCHELL PRUDDEN, M.D. Laboratory of the Alumni Association, College of Physicians and Surgeons, New York. New York: Trow's Printing and Bookbinding Co., 201-213 E. 12th Street. 1879.

DR. PRUDDEN has prepared these notes to aid the student in histological study, and has given him 128 pages of practical instruction, written in a clear and concise style. The introduction contains a description of the general methods for preserving tissues and preparing them for study. The body of the book consists of eighteen chapters, which are devoted to a histological outline of the structure of all the tissues in the human body, and a separate description of the method for their practical study. Students in histology and pathological anatomy are, for the most part, at a loss as to what book to purchase which will give them detailed directions, yet brief, regarding the successive steps necessary to be taken in order to properly prepare specimens for microscopical examination. In this little work, which its author so modestly places before the public, that knowledge regarding histological preparations can be obtained, and, being obtained, the student

stands upon a firm foundation upon which he can pursue pathological study. The book, for it is more than a pamphlet, should have an index, and should then be entitled, "A Practical Guide to the Study of Histology."

THE PHYSICIAN'S VISITING LIST FOR 1880. Twenty-ninth year. Philadelphia: Lindsay & Blakiston.

THIS familiar friend appears in its usual compact form—a *multum in parvo* to the general practitioner. Besides the customary calendar, poisons and antidotes, asphyxias, the metric system of weights and measures, and a table of doses, are among its contents. Among its blank leaves are appropriate headings for a visiting list, accounts, wants, obstetric and vaccination engagements, births, deaths, etc., etc.

A CLINICAL TREATISE ON THE DISEASES OF THE NERVOUS SYSTEM. By M. ROSENTHAL; with a Preface by Professor Charcot. Translated from the author's revised and enlarged edition, by L. PUTZEL, M.D. Vol. II. New York: Wm. Wood & Co. Library of Standard Medical Authors.

WE spoke quite extendedly of the merits of this book in reviewing the first volume. The second volume has the same qualities and methods of the first, but is somewhat more interesting to the reader, as it treats of the neuroses. These are divided into hysteria, spasmodic, cerebral, and spinal neuroses; neuroses associated with tremor and disorders of co-ordination; toxic neuroses, post-febrile nervous disorders, anæmic and reflex paralyses, and neuroses of the sexual organs.

In discussing these, Prof. Rosenthal is clear and systematic in his descriptions and just in his pathological views; but the American mind craves more of therapeutics than is generally given. Considerable is said about "water-cure," and a desirable addition would have been something definite about "climate cures" and "rest cures," which are becoming popular in American therapeutics.

Such things, however, are not, perhaps, very essential to a practical treatise that will go among the profession at large. The book, as a whole, is a sufficiently complete one, and ranks fully as high as any of the works on nervous diseases in the English language.

INFANT FEEDING AND ITS INFLUENCE ON LIFE. By C. H. F. ROUTH, M.D., etc. Third edition. New York: Wm. Wood & Co., 1879. Wood's Library of Standard Medical Authors.

DR. ROUTH'S work on Infant Feeding, first published in 1860, called attention at that time, in a way that had never been done before, to the terrible mortality among infants. He showed that one-fourth of all deaths was among children under one year of age, and, further, that one-half of these deaths were due to improper food or unhygienic surroundings.

With the stimulus of such an evil before him, and with an earnest enthusiasm in his subject, it is not strange that a most useful and effective book was produced. The present edition has received many additions which show that the question of infant feeding has been receiving much more care, both from public authorities and scientific investigators, since he first wrote. It is somewhat appalling, however, to see that there is as yet no great improvement in the total average of the mortality statistics. It seems that the pressure and complexities of a growing civilization keep pace with the efforts of sanitarians. Illegitimacy, infanticide, and maternal neglect or indifference, are evils which sanitary science can only try to counterbalance; it cannot strike at their root.

Dr. Routh divides his book into four parts, in which he considers: 1st, the causes of mortality and viability of infants; 2d, the subject of wet-nursing in its physiological as well as social relations; 3d, the general principles and practice of alimentation; 4th, the symptoms and treatment, dietetic, hygienic, and medical, of the diseases of defective assimilation.

The statement, quoted from Quetelet, that an infant just born has less chance of living a year than a man ninety years old, furnishes an impressive text to the subject of the conditions that make infant life so precarious. These are thoroughly gone over in Part I.

In discussing the subject of wet-nurses the author contends very strongly against the too prevalent habit of employing fallen women as such. Part III. contains a full discussion of the qualities and relative value of different kinds of milk, as well as of the various infant foods, artificial and natural.

Part IV. covers the question of defective assimilation more fully than in ordinary text-books upon diseases of children.

The book, as a whole, treats of the hygiene rather than of the diseases of infancy. As such it will be found a most valuable supplement to the standard text-books.

The author chills one's enthusiasm somewhat at the outset, by beginning his first chapter with a quotation from Tupper; but we find no further evidence of the influence of that favorite poet, and conclude that the quotation was but a passing vagary. It would certainly be distressing to find a poetical undercurrent of Tupperian philosophy running through a pædological treatise.

ANNUAL REPORT OF THE NEW YORK METEOROLOGICAL OBSERVATORY FOR 1878. By DANIEL DRAPER, Director, Central Park, New York.

THIS report contains abstracts from previous reports, showing some of the work which the Observatory has accomplished, descriptions of new instruments, a plea for a new observatory, and tables for the year 1878.

Much useful work is shown to be done at the Observatory, and the results of the observations taken there are in very general demand.

AMERICAN HEALTH PRIMERS. THE MOUTH AND THE TEETH. By J. W. WHITE, M.D., etc.

DR. WHITE, editor of the *Dental Cosmos*, has gone over his subject thoroughly, and made a very useful little book. It has not, however, much of interest to medical readers.

THIRD REPORT OF THE BOARD OF HEALTH AT NASHVILLE, TENN., for the two years ending Dec. 31, 1878.

THE Nashville Board of Health is a young organization, but it shows itself capable of excellent work. In their present report of 325 pages, there are twelve separate articles upon various topics. They evince much study and labor, and embody a large amount of useful information. Yellow fever is treated of in only one article, which is something of a relief to the Northern reader at least. The other papers cover the subjects of water-supply, school hygiene, sanitary geology, trees and shrubbery, mortuary statistics, etc.

The President of the Board is J. D. Plunket, M.D.; Secretary, J. B. W. Nowlin, M.D. The board has

one health officer two sanitary inspectors, and there is a third official position which in the unique nomenclature of the report is called 'Scavenger Boss.'"

CLINICAL LECTURES ON DISEASES OF THE URINARY ORGANS. Delivered at University College Hospital By SIR HENRY THOMPSON, Surgeon to H. M. the King of the Belgians, Emeritus Professor of Clinical Surgery, and Consulting Surgeon to University College Hospital. Fifth edition. Philadelphia: Lindsay & Blakiston. 1879.

It rarely falls to the lot of a medical writer to see the fifth edition of his work called for within eleven years, yet such is the fact with the volume we are called upon to notice. Sir Henry Thompson's works are so well known, and this one, especially in its former editions, has been so generally consulted by surgeons in this country, that nothing new remains to be noticed except in regard to two subjects, namely, stricture and lithotrity. In his second lecture "On some Points Relating to the Structure and Function of the Male Urethra," he throws the weight of his authority against "the too mechanical method of treating urethral disease," and says "that it originates in a want of consideration which appears very widely to exist as to the nature and functions of the urethra;" and again, "I note an increasing tendency to discover stricture, and especially to undertake a considerable amount of operative treatment for stricture of the slightest kind, and sometimes in cases where, in my opinion, no strictures have existed. There seems now to be a school which has determined for itself a very high standard of potency in what we hear called the 'urethral tube,' and which is accordingly said to have, or, if it hasn't, that it ought to have, a calibre of so many parts, and very large parts, of an inch, or so many millimetres, as the case may be. Instruments of astounding magnitude are produced, and if one of them cannot be passed, with an ease which contents the operator, through the whole of the urethra, the unlucky patient is pronounced to be the subject of stricture."

It seems hard for him to give his direct approval to the method of lithotrity advocated by Dr. Bigelow, of Boston, and now adopted by most urethral surgeons in this country. He says: "Of this proposal I feel compelled to say that, although the results may often be successful, it is to be feared that the result must sometimes be disastrous." The same may be said of any operation for stone, and a few lines lower down he says: "I am bound to say that my own system has for a long time past been gradually inclining to the practice of crushing more calculus at a setting and removing more débris by the aspirator than I formerly did."

There seems throughout the book to be almost an absence of the mention of anything American. Good work has been done by surgeons in this country in this department, which should have received at least some notice even in a course of "clinical lectures," which our author expresses the gratification of finding employed as a text-book in most of the medical schools of Europe, and translated for that purpose into the French, German, Italian, Spanish, and Russian languages.

The volume is well printed, and will certainly be sought for by those who pay any attention to diseases of the urinary organs.

THE LATE PROF. J. AITKEN MEIGS.—The students of the Jefferson Medical College have presented a portrait of the late Prof. Meigs to the trustees of that institution.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 28, 1879.

DR. E. L. KEYES, PRESIDENT, IN THE CHAIR.

THE MICROSCOPICAL COMMITTEE reported that the tumor of the testicle removed by Dr. Lente, and exhibited at the meeting of the Society, Oct. 22, 1879, was a cystic chondro-sarcoma, and that the tumors of the lungs and pleura presented by Dr Van Gieson were also sarcomatous, containing a trace of bone.

TUMOR OF PAROTID—ECCHONDROSIS OF INTEGUMENT OF NECK AND CHEST.

DR. A. C. POST exhibited a tumor removed by him from the parotid region, with the following history:

John S——, aged 63 years, applied to me a few weeks ago, with a hard tumor on the left side of the neck, having its upper extremity between the ramus of the jaw and the mastoid process of the temporal bone, and extending down the neck about seven centimetres. It is overlapped by the sterno-cleido-mastoideus muscle. The tumor is hard, and its motions are very limited. The patient first noticed it about four months ago. It began to be painful about two months ago, and the pain had gradually increased, so as to occasion great distress. His general health had suffered from continual pain and loss of rest.

November 17, 1879. I undertook the excision of the tumor. I made a free incision over its surface, from its upper to its lower end, dividing the skin, the two layers of the superficial fascia, including the platysma myoides muscle, and the deep cervical fascia. In order to expose the tumor, it was necessary also to divide the overlapping fibres of the sterno-cleido-mastoideus, which were closely adherent to the tumor, and seemed to form a part of its substance. The dissection was continued along the posterior margin of the tumor, which was found to be closely adherent to the adjacent parts. In order to expose the tumor more freely, a transverse incision was made across the middle of the longitudinal one. In prosecuting the dissection, most of the external branches of the cervical plexus of nerves were divided. The phrenic nerve was exposed to view, but was left intact. Near the upper part of the tumor, a large nerve was seen entering its substance, coming from between the styloid and mastoid processes, and believed to be the facial nerve. It was drawn down with a blunt hook and divided. The tumor was found to be so closely adherent to the great vessels, that it did not appear possible to complete the dissection without injury to the vessels. The pneumogastric nerve was brought into view, as was also the posterior part of the sheath of the vessels, the pulsation of the carotid being quite distinct. Under these circumstances, it was deemed expedient to divide the tumor, removing its lower part, including three-fourths of its substance, and leaving the upper part *in situ*. The wound was thoroughly washed with a carbolic lotion, 1 to 40, a tent for drainage was introduced throughout its whole length, and the edges of the wound were brought together with fine sutures. Cloths wet with the carbolic lotion were applied over the surface.

Nov. 19th.—The wound looks well; union by the first intention seems to have taken place throughout

a large part of its extent. Most of the sutures were removed, and the drainage-tent was taken out. The wound was syringed out with the carbolic lotion. As the patient was troubled with nausea and anorexia, he was directed to use nutritious enemata of milk and beef-tea alternately, at intervals of three hours.

There was no facial distortion, and the patient retained the power of closing his eyelids.

Nov. 22d.—A low degree of inflammation has spread from the lower part of the wound, over the clavicle, upon the upper part of the thorax. The lower part of the wound has reopened, and there is a discharge of offensive matter, with masses of gangrenous cellular tissue. On making an incision over the upper part of the chest, there was a further discharge of foul matter, with gangrene of the cellular tissue.

Nov. 24th.—The disintegration of the cellular tissue has also extended behind the clavicle into the upper part of the left pleural cavity, and there is a gurgling in that region during the acts of inspiration and expiration.

Nov. 25th.—The patient died rather suddenly, while sitting on a sofa in a room adjoining that in which he slept. He had from the time of the operation shown an aversion to remaining in a recumbent posture. Every day he had been out of his bed some part of the time, and had walked into an adjoining room.

No opportunity was afforded for an autopsy.

Dr. Post also exhibited a large mass of clippings from a diseased tibia, with the following history:

Fred. Lenckel, born in Pennsylvania, aged 25 years, admitted into the Presbyterian Hospital, Nov. 13, 1879. Nine years ago he began to limp on his right foot, with some pain and swelling at the upper part of the leg, near the insertion of the ligamentum patellæ. There was an increase of the pain and swelling during a period of three years, when the leg became flexed upon the thigh, and he applied to a surgeon, who etherized him and made an ineffectual attempt to straighten the limb. Six months later an opening was made, giving issue to a purulent discharge, and some small pieces of bone came away. The opening has never closed. When the patient was admitted into the hospital, there was found a ragged opening three centimetres in diameter, leading to an excavation in the bone. The opening was more than twelve centimetres below the upper border of the patella. A probe could be passed upward and backward six centimetres in the interior of the tibia, toward its articular extremity. From this opening there was an abundant discharge of pus, having an offensive odor. The patient presented a pale and anæmic appearance, but his general health was not very seriously impaired.

On the 15th November, two days after his admission, the patient was etherized, an Esmarch's bandage was applied, and I performed the following operation: I made a free crucial incision down to the bone, detaching the periosteum for some distance around the ulcerated opening, and then with chisels and gouges removed small pieces of softened bone, infiltrated with pus and with cheesy matter, making an excavation in the bone about as large as a goose's egg, being nearly twelve centimetres in the longitudinal axis of the limb, and nine centimetres in a transverse direction. The upper part of the excavation was separated from the knee-joint by a very thin shell of sound bone. The disease extended beyond the lower part of the excavation, but as the patient bore the anæsthetic badly, threatening symptoms of asphyxia having occurred, and as the operation had been quite protracted, it was deemed best to defer to a future day the removal of the remaining portion of diseased bone. On removing the Esmarch's bandage, there was a very copious oozing of blood from the whole surface of the bony excavation. To arrest this flow of blood, I stuffed the cavity with sponges which had been soaked in a carbolic lotion one to forty, and had been thoroughly squeezed, and applied a roller-bandage tightly from the toes up to the knee. The patient was then taken to his bed, and the limb elevated above the level of his body. After the lapse of four hours, the bandage and the sponges were removed, and as there was a slight renewal of the oozing of blood, the surface was carefully sponged, and a thorough application of liquor ferri persulphat. was made. This completely arrested the flow of blood. The cavity was then lightly filled with lint moistened with the carbolic lotion, and a roller-bandage was loosely applied.

Dr. Amidon thought that probably the exposure of the sympathetic was the cause of the sloughing.

Dr. Post did not believe that the nerve had been exposed.

ONE KIDNEY.

Dr. Stimson exhibited a specimen of almost complete absence of one kidney, and of malformation of the vagina. The subject was found in the dead-house of Bellevue, and no diagnosis had been made during life. The urine found in the bladder was free of albumen.

On opening the abdominal cavity, the absence of the left kidney was noticed. In its place was a calculous mass one and a half inches in length, and of the general shape of the kidney. The ureter of that side existed for about six inches, and ran from the bladder upward in a rather tortuous course, being lost in the neighborhood of the promontory of the sacrum. There was no left renal artery, but a small left renal vein. The bladder contained a sacculus as large as the thumb. The urethra was normal. The vagina was closed an inch below the os uteri by a diaphragmatic septum which contained two openings. Above the septum the vagina was large and roomy. The individual was apparently a virgin. There was no kidney structure found in the stony body occupying its place.

The right kidney, which had done the work for seventy-five years, weighed six ounces and a half, and had an adherent capsule. The left ventricle of the heart was somewhat hypertrophied; the mitral orifice was somewhat contracted, and there was considerable atheroma deposited in the aorta.

THE ORIGIN OF EPITHELIOMA.

Dr. Amidon presented a microscopical specimen of indurated tissue removed from the margin of an old ulcer, which seemed at one time to be degenerating into epithelial cancer. The subject was an old soldier who had been wounded during the late war, and the ulcer had existed ever since that time. It was finally healed, however, by the application of an ointment composed of salicylic acid and balsam Peru, and the use of the elastic bandage. At the time when the ulceration presented its most suspicious appearance the specimen was removed.

On microscopical examination it showed a great proliferation of cell-element, and a marked hypertrophy of the mucous, epithelial, and papillary layers of the skin; but in no place were the characteristic cell-nests to be found.

Dr Arnold took occasion to refer to the connection that is said to obtain between degeneration of the epithelioma and destruction of the cells of the part. There was often a proliferation of the cells of the rete mucosum and at the base of the papilla, that the vascular supply was cut off. The upper portions of the papilla in their turn became hypertrophied, until they eventually came in contact with each other, shutting in the cell growth below, where cell nests were eventually.

In answer to a question from Dr Post, he stated that warts were generally present a long while from this degeneration, from the fact that the natural pressure to them prevented the growing of the cells below ment and the consequent formation of cell nests. When these fissures became close there was great danger of cancerous degeneration.

Dr. Simmons remarked that such a theory did not hold good in all cases, as sometimes the proliferation of cell element took place downward, and the section of the disease very often presented an uneven and ragged outline below the base of the papillæ.

Dr. Kerrs referred to a case of chronic ulcer, which was said by a competent microscopist to have degenerated into epithelioma, but which was cured by strapping. In that instance the usual cell-nests were found.

The Society then adjourned.

WEST CHICAGO MEDICAL SOCIETY.

Regular Meeting, Nov. 10, 1879.

TRAUMATIC TETANUS — TWO RECOVERIES.

Dr. J. H. Salisbury reported two cases, one of which recovered.

The first was a lad of 16 years of age, who had been previously healthy except that he had experienced small-pox in childhood. One brother was said to have died of tetanus. He received a wound on the face by the kick of a horse; he did not lose consciousness, and was able to walk home. The wound was closed by Dr. Lee, with needle sutures, and dressed with carbolic acid lotions. On the third day the needles were removed. The case did well till the fifth day, when slight stiffness of the muscles of the jaws announced the presence of tetanus. This symptom grew gradually worse for three or four days, during which time dysphagia gradually came on. The next day (the fifth of the trismus) he was admitted to the County Hospital. Then it was found he had difficulty in speaking; on every attempt the muscles of the mouth were thrown into spasm, "the features assuming at times a true risus sardonicus." The front teeth could be separated only a centimetre; the dysphagia was severe, owing to spasm of the muscles of deglutition.

There was no fever; the wound was in good condition. He was given a cathartic at once, and was prescribed forty-five grains of bromide of potassium, and fifteen of chloral every four hours.

He continued in much the same condition, having frequently slight spasms affecting the muscles of the neck and mouth, while there was a certain stiffness of these muscles constantly present, until the fourteenth day, when a paroxysm occurred to which there was spasm of the respiratory muscles and closure of the mouth, insomuch that the patient became distinctly cyanosed, and slight opisthotonus also took place. In a few hours another similar paroxysm occurred, after which he was more quiet for a day and a half.

Then occurred a spasm more severe than any of those described. Now a dose of bromide of potassium of two drachms was given, followed by half-drachm doses every two hours. Next day another profound paroxysm occurred. On this day, the thirteenth of the tetanus, the administration of calabar bean by hypodermic injection was begun, a quarter grain of the extract being exhibited every two hours. Meanwhile the chloral and bromide were continued. From the time the paroxysms ceased. The calabar bean was used until the circulation showed signs of depression, yet the pupils were not contracted.

There was at no time any fever. The wound healed kindly, and the patient was discharged well three and a half weeks from his admission.

The second case was of a man who had received a crushing injury of the foot without breaking the skin. Hot water dressings were applied to the injury. In five days symptoms of tetanus appeared in the jaw, and he was given bromide of potassium and chloral. Thirty-six hours afterward he was admitted to the hospital, when he was immediately put upon the treatment of bromide of potassium and chloral, thirty and fifteen grains respectively every two hours, and every hour a hypodermic injection of one-eighth grain of extract of calabar bean. A tablespoonful of whiskey was given every hour. Paroxysms of muscular spasm with some opisthotonus occurred every half hour, when the patient was quiet. A trifling disturbance would at any time precipitate a spasm.

Two days after admission, difficulty in swallowing appeared. Seven hours afterward a severe paroxysm occurred, followed by rapid breathing, rapid and weak pulse, unconsciousness, and in an hour the man died without a struggle.

There were, up to the moment of death, tonic spasms of the muscles, which had shown no relaxation from the effect of the medicine given; the pupils were not contracted to any extent during the sickness.

Dr. S. thought the manner of death was curious, and queried whether it could have been due to the calabar bean.

Dr. Henry Van Buren next reported a case of tetanus with recovery.

The patient was a man 23 years old, a laborer, with good previous health. He received a wound of the ball of the left thumb by a circular saw in motion, September 27th. The wound was small, but deeply torn; the bone was not injured. The wound was first dressed by another surgeon with some compound resembling pitch, which caused pain; this dressing was removed by Dr. Van B., and replaced by simple adhesive plaster, and the patient went to work feeling comfortable. In two or three days the dressings were removed. In six days from the injury the patient presented himself, complaining that he could not open his mouth. The next day more positive symptoms of tetanus were present. "Simultaneous spasms of the whole body" occurred frequently. The jaws became fixed, so that an opening between the incisors could be made of only one-eighth inch.

The muscles most involved in rigidity were the masticatory, those of the neck, chest, and the flexors of the extremities. Among those most involved in the spasms were the muscles of the face, so that extreme opisthotonos was produced. Photophobia was present throughout, and bright light would increase the frequency and severity of the spasms; and unexpected sound had the same effect.

The spasms became so frequent by the second day, that they occurred every thirty minutes, and it was not till the seventh day they became less frequent;

they did not entirely cease till the fourth week. Great pain was experienced in the paroxysms.

There was little fever. The pulse was about 100 most of the time. The mind wandered at times, and the sleep was of course broken by the frequency of the paroxysms. The face was flushed. At the end of the fourth week, mastication was free for the first time.

The treatment consisted of extract of calabar bean, one-half grain every two hours, for two days, with doses of bromide of potassium and chloral, fifteen grains each, every two hours, alternating with the extract. On the third day the extract was given every three hours, and morphine was added to the treatment as pain seemed to indicate, as much as half a grain being given hypodermically at a dose. Now the spasms became less, both in frequency and violence, and contraction of the pupils came on for the first time. During the fourth and fifth days the chloral was omitted, and the extract of calabar bean given every four hours.

On the seventh day (at the suggestion of Dr. Bridge) the morphine was omitted and the calabar bean given every four hours; at the end of forty-eight hours the pupils were slightly contracted—then the morphine was resumed. This treatment was kept up till convalescence was established. Linseed-meal poultices were assiduously applied to the wound.

The patient was present at the meeting, and was exhibited.

His limbs, especially the lower, were stiff, and their motions apparently abbreviated. On rising to walk, he found great difficulty in raising his feet free from the floor, and in moving forward dragged or shuffled them forward. No pain was experienced, and after an effort of a few minutes his gait would become more free. Sensation was perfect.

The head was slightly projected forward.

Dr. H. M. Lyman, in discussing the reports, said tetanus was due to an inflammation of nerves propagated from a wound at the periphery to the nerve centres. The treatment that offered the most hope was such as would prevent the paroxysms of muscular spasm while it lessened the force of inflammatory action at the centres.

Dr. Millard reported verbally a case of tetanus in a child two and a half years old, resulting fatally. The treatment was with chloral and bromide of potassium.

Dr. O. J. Price also verbally reported a case of tetanus in a boy of fifteen, who had received a wound of the scalp. On the tenth day trismus appeared, followed by well-marked tetanus. The spasms occurred every few minutes. The treatment was with chloral and calabar bean. In six days the patient died. The temperature before death reached 103° F.

Dr. Chas. D. Camp read the history of a case of what was, in the absence of any post-mortem examination, supposed to be abscess of the liver, breaking into the lungs and resulting fatally.

Hard Chemical Names.—Dr. C. writes: "It is germane to your recent item in relation to present chemical nomenclature to say that the *Berliner Chemische Gesellschaft* of October 13th last contains a note on the production of tetramethyldiamidodiphenylmethan and naphthyldimethylamidophenylsulphon. If the latter is heated with nitric acid, pertanitrodimethylaniline and nitronaphthalinesulphite are produced."

Correspondence.

CONCERNING SO-CALLED PATENTED ARTICLES.

To the Editor of the Medical Record.

Dear Sir:—In his reply, "Pharmacopœia," although "infinitely obliged" to the writer "for his construction about patented and trade-marked articles," is still surprisingly deficient in understanding the real point at issue. While he concedes that the articles named in his former communication were erroneously classed by him as (to be) patented, and admits that there is *no worthless or dangerous preparation in the market which is patented*, he cannot consent altogether to leave patented out of connection with trade-marks, for he is tempted to say: "A trade-mark is a partial patent at least," etc. Now, sir, permit me to state that this is out of reason entirely; for such a thing as a "partial patent" does not exist in any case—it cannot exist! "Partial patent" is a new word, coined by "Pharmacopœia," which shows evidently that he has not yet entirely mastered the subject, simple and plain as it is. In connection with this, I should not omit to mention that in his reply "Pharmacopœia," to my amazement, is led to use the word "quibble." This is hardly in keeping with the avowed spirit of his communication. Further, being ready to "proceed to the more important and serious side of the question," with all this seriousness and importance he really parades again his spiritual offspring, the "partial patent." The remainder of his answer contains remarks which do not belong to our controversy, and therefore I leave them unnoticed. I never, in a discussion, take up a new point before the original issue is satisfactorily settled. That "Pharmacopœia" has not arrived at that point needs not to be further proven.

Yours respectfully,

Julius Fehr, M.D.

Hoboken, N. J., Dec. 18, 1879.

THAT ODD CENT IN THE YELLOW FEVER FUND.

To the Editor of The Medical Record.

Sir:—The enormous or rather curious sum of one cent, has appeared in every report of the Yellow Fever Fund of the Medical Society of the County of New York, to the no little merriment of the members. It was thus obtained: The Medical Society of the State of South Carolina sent a check for $443.45, and the mayor of New York gave another for $179.56. All other sums received and paid out were in dollars, with no cents; hence that one cent, which was obtained from the addition of 45 cents to 56 cents, remains, and probably will remain to the end.

All the beneficiaries of the Society were heard from shortly before Christmas, and all were remembered; none are suffering at present; while most of the 26 widows and 51 orphans whom we have helped, are now self-supporting. The committee still has $1,073.01, from which $25 per month is being sent regularly to four of the beneficiaries; while we have three other worthy widows, with eleven children, whom we are striving to help with larger sums.

When the last dollar is distributed, I hope to be allowed to retain that *one cent* in remembrance of the fund.

J. C. Peters, Chairman.

New Instruments.

A NEW INSTRUMENT FOR THE REPAIR OF LACERATION OF THE CERVIX UTERI.

By ELY VAN DE WARKER, M.D.,

SYRACUSE, N. Y.

The importance and usefulness of repair operations upon the vaginal portion of the cervix uteri is interfered with by some mechanical difficulties in its performance, which have confined the operation to the hands of specialists. The theory of the operation is a very simple one, the instruments needed are few and inexpensive; no minute anatomical knowledge is involved in its performance, and yet, like the operation for vesico-vaginal fistula, it has never been popularized. The reason is that the operation is mechanically difficult. The difficulty attends but one step of the operation: the passage of the sutures accurately at the place needed. The denudation of the lacerated edges usually presents but few obstacles to a speedy completion of the operation.

In the case of a soft and yielding cervix the introduction of the sutures is comparatively easy and speedy, the only delay arising from the necessity of keeping the blood well sponged away in order to see where to plant the needle, and the point toward which to urge it. But, in case of an hypertrophied and indurated vaginal portion, the introduction of the sutures is sometimes exceedingly difficult. Especially is this the case with the first stitch, which, if placed correctly, is introduced so far back that the needle, in passing, is just seen at the bottom of the laceration, and in order that the needle may emerge at a point opposite that of its entrance, it must describe part of a circle through the indurated tissues. This is because needles are made curved, instead of straight, as they ought to be, in order to pass easily through tissue so dense as is found under these circumstances.

By the use of the little instrument here figured all these annoyances disappear. I call it the suture forceps. It consists of two parts, the male blade, *b*, Fig. 1, which carries a straight needle 2.4 cm. long, secured at *d* by a set screw, and the female blade, *a*, secured to the male blade by an open slot at the joint *c*, like the lock of an obstetrical forceps. At *c* is another slot, through which the needle passes. Both these slots are better shown at *a* and *b*, Fig. 2, of the female blade. The opposing surface of the female blade has two blunt spurs at *e* for the purpose of preventing slipping while the blades are closing.

The most novel feature of the instrument is the eye of the needle, which is placed in the point, like that of a sewing machine needle. As it would be exceedingly difficult to arm this needle after it has passed through the tissues, obscured by blood, with either wire or thread, it is provided with what I may call a self threading device. The eye of the needle is placed at a right angle to the blades of the forceps, at the side further from the operator—in the direction *c*, Fig. 1—a delicate slot is cut through the side of the needle into the eye further from the point. After the needle is passed through the cervix, the operator has but to make a loop in the wire or thread, throw it over the point of the needle and draw it upward; as it moves along the needle it is caught in the slot and falls into the eye. The use of the instrument is very simple. The two blades are lying separate by the operator. He picks up the male blade, puts the point of the needle at the place he wishes to make a suture, and then taking the female blade, places the distal end on the opposite side of the cervix; its slot is then passed under the button at the joint in the male blade and the instrument locked. The forceps is now held lightly in the grasp of the left hand, and with a tenaculum in the right hand, that portion of the cervix opposite to that held by the point of the needle, is drawn down parallel to it, at which moment the forceps is closed. The loop is now passed over the point of the needle and drawn along its shaft until it drops into the slot. The forceps is unlocked, the slot in the distal end at *b*, Fig. 2, is carried away from the end of the needle, so that the wire loop—if wire is used—is both compressed and carried into the eye of the needle at the same time. The eye is thus armed without being seen by the operator.

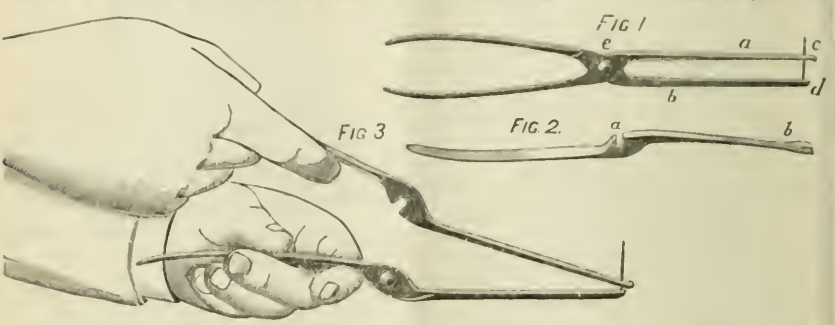

Fig. 3 shows the further use of the two blades. The slot in the distal end of the female blade is passed along the male blade till it is stopped by the needle, and thus acts as a counter-force while the needle is being withdrawn from the tissues.

The speed with which work may be done with it is remarkable, contrasted with the old method.

One word as to the shape of the needle. I have heard very experienced gynecologists remark that the suture material ought to fill up the kerf of the needle. This depends entirely upon the point of the needle. If it is lance-shaped and sharp it will cut its way and consequently bleed; if, however, its point is blunt and rounded, or flattened, it will tear its

way, spreading the tissues as it passes through, and allowing them to recoil, as it were, upon the wire directly it has passed. This fact is taken advantage of in the construction of the suture forceps.

Mr. John H. Christman, of Syracuse, has my model, and can reproduce the instrument at a small cost for those who wish to try it.

A NEW ASPIRATING AND EXPLORING NEEDLE.

By CHARLES A. HART, M.D.,

PLAINFIELD, N. J.

For a number of years I have been in the habit of using an ordinary hypodermic needle and syringe for the explorations of diseased joints and tumors of various parts of the body, thought to contain fluids, and also to empty the pleural cavities of collections of serum, but having had unpleasant results follow its use in some cases from the cutting edge of the needle, I devised a needle fitted to the ordinary hypo-

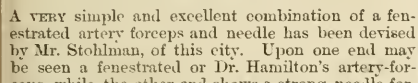
dermic syringe, *round-pointed*, with a small fenestrum on the side a short distance from the point. In exploring a joint or tumor, the needle is attached to the syringe and introduced into the growth or part. A withdrawal of the piston will fill the barrel of the instrument with the desired fluid. Upon the removal of the needle, the minute point of puncture closes at once.

I have explored an immense aneurism of the abdominal aorta with the above-described instrument, in which a doubt existed as to the nature of the growth. The examination determined the diagnosis. No bleeding occurred from the point of puncture. At the autopsy, two weeks after the exploration, there was no sign of the point of puncture; no leakage occurred from the sac, nor were there any signs of local peritonitis. From the above test, I should feel no hesitancy in exploring *any* of the cavities of the body to relieve pressure or confirm a diagnosis.

The instrument is manufactured by Mr. William Ford, of Caswell, Hazard & Co., New York City.

A NEEDLE- AND ARTERY-FORCEPS COMBINED.

A very simple and excellent combination of a fenestrated artery forceps and needle has been devised by Mr. Stohlman, of this city. Upon one end may be seen a fenestrated or Dr. Hamilton's artery-forceps, while the other end shows a strong needle-forceps, similar to the point of Dr. Sands' or Dr. Prout's instrument. The jaws, inlaid with soft metal,



grasp the needle with great power without danger of breaking its eye or injuring its point when extracting the same. The instrument takes up no more room in the pocket-case than the ordinary artery-forceps, nor is the expense materially increased. One of the principal advantages will be, that two such very useful instruments, combined in one, will be always at hand and convenient.

THE CUTIPUNCTOR.

By SAMUEL SHERWELL, M.D.,

BROOKLYN, N. Y.,

LECTURER ON SKIN DISEASES, LONG ISLAND COLLEGE HOSPITAL, VISITING PHYSICIAN TO THE BROOKLYN CITY HOSPITAL, ETC.

The subjoined woodcut is a representation of an instrument designed by myself for the cure of cutaneous nævi, and for which the name of cutipunctor has been suggested. It is used, as the name would indicate, for puncturing the skin in cases of cutaneous nævi, and simultaneous introduction into that tissue of some fluid that will more effectually plug up the divided and lacerated capillaries, and cause adhesive inflammation in them.

A similar, but much more rudely made instrument has been used by me hitherto with success in these cases; and I have read papers and shown cases on the subject before both the New York and American Dermatological Societies, which papers have been published in both cases in the *Archives of Dermatology*, vols. iii. and iv., pp. 214, 354.

It is sufficient here to say, in brief, that the modus operandi is as follows: The patient being anæsthetized, or not (seldom necessary), the *business end* of the instrument can be graduated to any degree of depth of penetration necessary, by the screw-cap, the bundle of needles being dipped each time into a sponge saturated with the fluid thought best (carbolic acid, 80 per cent., chromic acid, 20 per cent., the solutions mostly used by author), the instrument is kept with firm pressure on the part, and, the spring being let go, the needles penetrate, carrying a modicum of the solution with them. The needles are the ordinary straight saddler's needle, of small size, but grooved far down on each of the three sides.

As many piercings may be allowed as shall be judged necessary. It is well to be cautious at the first operation, as skin differs markedly in tolerance in different individuals; the extent of nævus must also be taken into consideration. As may be imagined, the difficulty of cure and length of time necessary is in inverse ratio usually to size. I think a spot about a square inch could be removed, or rather caused to disappear, certainly with one or two operations.

The after-treatment is believed to be equally important, when, after sufficient use of the instrument, the bleeding and oozing of bloody serum is stopped, as it may be very soon by the firm pressure of linen cloth, or pad of blotting-paper, the part cleansed and wiped off quickly with a little alcohol; a moderately concentrated solution of collodion is applied in successive coats—say two or three—over the part operated upon, with a view to compression of the tissues, thus effecting, possibly, a comparative ligation of the wounded capillaries, and their occlusion from adhesion, etc.

I have used the instrument several times since I received it, about a fortnight since, in cases of retained placenta and abscess, and can recommend it highly. The case is for sale by the makers. It would be superfluous to say that it is well made, easily cleaned, and efficient.

I have been using the foregoing method to all parturients since 1874, with marked success in many cases, entire in others, and believe that in the number of needles used, their arrangement and modification, and their distance from each other; also in the employment of medical escharotics in this manner, and the after application of collodion, are original, certainly the last two, as have not for the purpose indicated, applied.

I have here to use all the word "tattooing," when writing on this subject, without, of course, meaning the word in its exact application as regards tattooing-staining, but as being best suited to convey the idea of operation.

151 Roman Street.

Medical Items and News.

Death from Chloroform.—We are much indebted to Mr H. H. Robinson, House-Surgeon of the General Infirmary, Hull, for the report of a death from chloroform which occurred in that institution last week. The facts of the case are, briefly, as follows: The patient, a powerfully built country laborer, was admitted under Mr Craven with a disorganized eyeball, the result of old injury. He came to the hospital for the purpose of having the eye removed, and, on November 21st, this was done by Mr Craven. Chloroform was administered on a towel by Mr. W. H. Smith, one of the assistant house-surgeons, and the patient was quickly under its influence, without a struggle. The operation was then proceeded with and completed in something less than five minutes, the effect of the chloroform being kept up during part of that time. When on the point of dressing the eye, the patient suddenly ceased breathing, and his face became livid. The tongue was at once pulled forward, and artificial respiration resorted to. Galvanism and nitrite of amyl were also tried, but unfortunately without success. So far as can be judged, the patient had not inhaled any of the vapor for three or four minutes previous to the respiration ceasing. Mr Smith states that when the administration was stopped the pulse was a fairly good one. *Post-mortem*, beyond intense congestion of the kidneys, nothing was discovered to throw any light on the case, the heart and lungs being apparently perfectly healthy. Mr. Robinson says that chloroform has been administered daily in this hospital for many years, and only once previously, twenty-five years ago, with fatal effects.—*British Med. Jour.*

The so-called Pneumonia following Croup.—Our attention has been called to an ambiguity of expression in the report of Dr. Ripley's remarks at a recent meeting of the New York Pathological Society, which was due to the omission of a period, and the consequent joining of two distinct sentences. The clause to which we refer should read thus—page 536, line 32:

"An autopsy shows inflated and anæmic lungs, with here and there a patch of collapse. Membrane lines the tubes to a variable extent, completely plugging those branches leading to collapsed lobules."

Treatment for Chronic Rheumatism.—In response to a request in the *Medical Record* for some efficacious remedy in cases of chronic rheumatism, the following letter was received from Dr. J. Camp, of Michigan:

"Up here in Michigan we have a summary way of disposing of such cases. I am sixty-one years old; have practised medicine nearly forty years; have had chronic rheumatism for thirty years. For the last ten or fifteen, when a man or woman comes to me with chronic rheumatism, I take down my double-barrelled shotgun, and say, 'Get out of here, or I will blow your brains out!' This may be called the Traumatic method.

The New Edinburgh Infirmary.—The new Edinburgh Infirmary, just completed, is, according to the *Philadelphia Medical Times*, the finest hospital in the world. It is built on the three-story pavilion plan, with the medical and surgical parts entirely separate. It contains 571 beds, and the total cost is $1,700,000. Impervious paints and varnishes have been used to make the walls and floors non-absorbent. No expense has been spared to make the structure perfect in every detail.

Pleuro-pneumonia.—Two new outbreaks of this disease are reported, one at Yonkers and the other at Haverhill, N. H. In the former place, eighteen cattle have died from the disease within the past few weeks. In New Hampshire the governor has appointed a commission to take such action as may be deemed necessary in case of the spread of the disease.

In this connection it may be noted that the United States Veterinary Association, which some time ago advocated the establishment of a National Veterinary Sanitary Bureau, has prepared a petition, praying Congress to provide such a bureau.

Cremation.—The crematory of Dr Le Moyne at Washington, Pa., has recently been used again—this time on the body of a New York gentleman who died of phthisis.

Infant Mortality in Paris.—Owing to the growing increase in the death-rate of children of tender years in Paris, the Minister of the Interior has written a circular to the Prefects, ordering them to draw up regular reports as to the causes of the alarming mortality.—*Medical Press and Circular.*

Candidacy for St. Bartholomew's Hospital.—Professor Lister and Mr. Jonathan Hutchinson are said to be candidates for the surgeoncy at St. Bartholomew's Hospital, left vacant by the death of Mr. Callender.

Rush Medical College.—A concourse for the lectureship on gynæcology in the spring course of lectures in Rush Medical College will be held Jan. 6, 1880. Applications for admission thereto received from "regular" physicians only. All who desire to compete for the position are requested to apply to the secretary, who will assign subjects and furnish any desired information relating to the conditions of the concourse. At the last spring session of lectures, 148 students were enrolled; already 133 have matriculated for the same session.

J. H. Etheridge, *Secretary.*

Original Lectures.

ON SUBACUTE AND CHRONIC NON-SUPPURATIVE INFLAMMATION OF THE TYMPANUM AND EUSTACHIAN TUBE.

A Lecture Delivered at the Manhattan Eye and Ear Hospital.

By OREN D. POMEROY, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, AND TO THE NEW YORK FOUNDLING ASYLUM.

Gentlemen:—The subject which I have chosen for this evening's lecture I would denominate as Subacute and Chronic Non-suppurative Inflammation of the Tympanum and Eustachian Tube. This disease may be simply the remains of acute inflammation either in the tympanum or in the Eustachian tube. Generally we expect acute inflammation of the tympanum to be more or less self-limiting, and if the subject have a constitution which is not tuberculous, or affected with any dyscrasia, the disease goes on to a satisfactory termination, leaving nothing behind it. But frequently this is not the case, and the lingering inflammation remains after most of the symptoms have been subdued, and it is proper to denominate this subacute or chronic non-suppurative inflammation of the tympanum. A catarrh of the tympanum dependent upon taking cold may not differ in kind in the least from the fierce acute inflammation of the tympanum; the difference is in degree only. Again, an ordinary suppurative inflammation of the tympanum may recover completely, leaving the ear in a condition more liable to take on inflammatory action than before. In other words, the ear is a weak point, and if the patient takes a slight cold, the ear is much more likely to be affected than if the patient never had had any trouble with it, and we have the disease again developed in that ear. Many of the causes of acute inflammation apply equally well to these under consideration. For instance, exposure of the head and ears to cold in a general way, more especially if the patient is sitting at an open door or window, or listening at a draughty key-hole, and the air blowing in upon him, produces the inflammation we are speaking of. In the early period of the affection there will be a moderate secretion, but after a while the mucous glands may become atrophic and many of them destroyed, so there is very little, if any, discharge; and it might then be denominated dry catarrh, or, as some define it, "a proliferous inflammation of the tympanum,"* which I believe to be the latter stage of the same affection.

The symptoms in general I will divide into *subjective* and *objective*. The subjective symptoms are hardness of hearing, tinnitus, vertigo, defective memory, dulness of mental perception, unnatural sound of external noises, etc. Hardness of hearing depends upon hyperæmia and thickening of the lining membrane of the tympanum, and to sunken drum-membrane, with what we call impaction of the base of the stapes in the oval window. This you will readily see is due to difference in the air-pressure on the outer portion of the drum-membrane and the inner. The membrane of the round window is also put upon the stretch, the bulging being toward the tympanic cavity. The lowering of the hearing is accomplished in this instance by interference in the passage of the sonorous undulations to the labyrinth consequent upon this pressure, which, by the impaction of the stapes in the oval window, compresses the labyrinth water, and through this the terminal filaments of the nerve.

A word as to how the Eustachian tube becomes closed. Frequently it is closed by a collection of mucus in the faucial portion of the tube, but generally it is closed by a catarrhal swelling of its mucous lining, thus diminishing its calibre. Tinnitus depends very largely upon the above-mentioned pressure. Later on there may be present an unnatural sensitiveness of the nerve, so that every pulsation of the artery is painful, or invariably noticed, in which instance we have what may be called pulsatory tinnitus. That is, every time the heart beats the tinnitus is a little exaggerated. The symptom of vertigo depends almost altogether upon the same pressure which produces deafness and tinnitus.

The altered sensation in the tympanum and Eustachian tube is a very interesting phenomenon, but difficult to define, being much easier for a patient to observe himself than for any one to describe it. It is safe to say there should be no *sensation* in the ears. If there is sensation present, they are imperfect. When studying diseases of the heart you observe that a patient became conscious of its action only when it became diseased. Just so with the organ of hearing, its functions should be performed unconsciously. A crackling sound is often noticed in the tympanum during deglutition, or when the patient sneezes or coughs, and it is a little difficult to give a satisfactory explanation of this. The readiest explanation is, that there is a difference of air-pressure in the tympanum and throat, and whenever the patient swallows the tube is open and there is a rush of air to or from the tympanum, according to the location of greatest air-pressure. Again, in this disease the tube is much more readily *forced* by any excess of air-pressure in the pharyngeal space, owing to the relaxation of the mouth of the tube, by which its valvular opening is so changed that it no longer prevents the air from rushing in.

Another Symptom.—Sounds cause peculiar sensations upon the ear in this condition. They will be muffled, or be hollow and reverberating, and hence extremely disagreeable. Again, the patient may feel as though there were something in the ear which he might remove by shaking the head; it is something which annoys him rather than pains him. Occasionally we may have a throbbing sensation, and sometimes pain. The latter is not constant, and is liable to be of the darting variety. In the Eustachian tube there may be soreness or slight pain.

Objective Symptoms.—First, of the membraua tympani; and second, of the Eustachian tube. The meatus in the early stages may be smeared with cerumen, which is either too thin or too thick. It may be in considerable quantities, even to the degree of impacted cerumen. You remember when talking upon these cerumen cases I told you that a very large number of them had disease of the ear, and the presence of the cerumen seemed to be an important symptom of disease. The opposite condition also obtains. Later on there may be complete absence of cerumen from the ears, and I should explain it in this way: earlier in the disease there is a hyperæmia, you might say irritable and hyperæmic ceruminous glands; they secrete too much, which is altered in quality. After awhile they become anæmic and atrophic, and the secretion is diminished. The epi-

* Dr. Roosa.

dermis of the drum membrane is frequently lost—and, more or less detached, and occasionally slightly lacerated, thus giving the membrane a scruffy appearance. The meatus may be tender, reddened, with other indications of a subacute inflammatory process going on. You have all noticed that the external meatus is extremely sensitive to rough handling; and if there is a certain amount of inflammation present it will be still more sensitive. The membrane may look natural in color, or it may be reddened; the redness is always moderate, and is in the vicinity of the short processes, extending down along the malleus handle, with frequently a little peripheral injection of the membrane. Sometimes minute blood-vessels may be seen shooting in toward the centre. The membrane may be opaque, giving a whitish appearance. You remember, probably, that I told you that the drum-membrane should be gray and translucent, somewhat of the appearance of mother-of-pearl, and when looking at it you are conscious of seeing into its depth. This will be absent, and you have a tolerably that appearance when it is opaque. The light spot is usually small in size and frequently changed in position. Instead of forming an obtuse angle with the malleus handle, it will form a right or an acute angle, or even extend in the direction of the malleus handle, or may be displaced to almost *any* portion of the membrane. Frequently in excessive sinking of the membrane I have seen it pushed inward quite near to the periphery, giving a linear reflex, the line being parallel to the periphery of the drum-membrane. You occasionally have a light spot upon the most projecting portion of the short process; the light spot may be entirely absent from the loss of polish of the dermoid layer of the drum-membrane from changes which I have hinted at. It may be altogether too bright. The explanation of the latter may be somewhat fanciful. It is as follows: any inflammation of the mucous lining of the tympanum may not extend beyond the lining of the drum-membrane, the fibrous and dermoid layers remaining usually translucent, while the mucous layer is rendered opaque by the inflammation. A larger amount of light is thus reflected than usual, and we have a bright, glistening appearance, almost as bright as the reflex from fluid, but not quite. The malleus handle is foreshortened—that is, it is pushed inwards, and you see it obliquely. The inclination may be, and frequently is, unnatural. It will be too vertical or too horizontal. I will explain the change in the direction of the malleus handle as follows: the position of the anterior pyramid varies. It may be more posteriorly placed than usual, and retraction of the tendon of the tensor tympani will have a tendency to drag the malleus handle backward, making it too horizontal. On the contrary, if it is placed too anteriorly the tendency will be to draw it in a more vertical direction.

The processus brevis is almost always seen too prominently. There are several explanations for this, but I will give only one. The drum-membrane falling over it causes it to appear prominent, the same as if we wet our clothing; it settles down and reveals the contour of the body better than in its ordinary condition. The anterior and posterior folds are often exaggerated, more frequently the anterior. The anterior portion of the membrane is often seen in shadow, and a little darker colored than it ought to be, which is due to sinking of the drum-membrane and its being dragged out of the light. All these conditions are found, sometimes, upon the sunken drum-membrane. Occasionally we see signs of fluid. It is very difficult, indeed, however, to clearly determine positively when present. The drum-membrane looks a little more opaque and a little grayer; perhaps you will see a change in color which will be separated by a sharp line, indicating the height of the fluid. By moving the head backward and forward, a change in the line will be observed. If the head is thrown to the opposite side, it may disappear altogether, from the fact that the fluid recedes entirely from contact with the drum membrane.

Symptoms observable in the Eustachian Tube.—In general terms we are likely to have some form of diseased throat. It may not be sore. The patient may have a considerable amount of tubal catarrh without any accompanying sensations, and you will surprise him by a statement of the condition of things. I will enumerate some of the more frequent conditions met with. The color is usually intensified, the papillæ much hypertrophied, enlarged and somewhat varicose veins may be seen. Again, we may have what is called relaxed throat, it will be pale, there will be little or no swelling, and accompanied by the secretion of a thin, mucous discharge. Another form which would come under the head of dry catarrh is where the back wall of the pharynx is very red and dry, and glistening as if varnished. The mucous glands seem to be destroyed by atrophy—the disease most likely to accompany dry or profuse otitis. Enlarged tonsils are frequently observed; the velum pendulum may be swollen and œdematous, it may be too large, or it may be shrunken up, terminating in a sharp point. The appearances of the Eustachian tube are a little more difficult to observe an exact idea of them necessitating the use of the rhinoscope. I will enumerate some of the appearances of the tubes as seen by rhinoscopic examination:

I. Mucus in the mouth of the tube, with or without greenish or grayish mucus clinging or adherent to the post-nasal septum, and occasionally filling the nares.

II. Increased redness in and about the mouth of the tube, or paleness of the mucous lining of the part.

III. An œdematous condition of the parts near to and in the mouth of the tube, resulting in more or less swelling.

The swelling in the region of the tube, the result of hyperæmia or œdema, may: 1. So far obliterate the mouth of the tube as to cause it to appear as a minute dimple, or obliterate it entirely; or, 2. Produce so much swelling of the collar-like surrounding of the tube as to greatly exaggerate it. 3. Increase of the elevation which separates the mouth of the tube from the fossa of Rosenmüller. 4. Enlarge the posterior extremities of the middle and inferior turbinated bones, causing a malposition in the posterior nares, and gives them a rough and uneven outline. 5. Cause a ring-like swelling around the tube—rough, red, and of a macerated appearance.

IV.—Granulations similar to those found in the pharynx in granular pharyngitis near the mouth of the tube.

V.—Polypi in the posterior nares, and more frequently on the turbinated bones.

VI.—Whitish striæ, indicating cicatricial degeneration of the proper substance of the mucous membrane in the region of the Eustachian tube.*

Prognosis and Results.—Mild cases may entirely recover, especially in young subjects. The great trouble, however, is the disposition to relapse. I know of no disease that relapses so frequently. It

* From Dr. Roosa's Treatise on the Ear, communicated by the author of this lecture.

relapses whenever the patient takes cold, or if exposed to cold, and in this vicinity it is safe to say that harsh and irritating air frequently gives rise to the affection. Cure your patient, and again expose him to the same influence which first caused it, and the disease is likely to develop again. In this vicinity I find the air of Brooklyn and Jersey City worse than that in New York—the New York air being as mild in winter as any air I know of. A number of cases never become cured. These are among the adult and aged. We wish to head off the disease, the tendency being to become constantly deafer. It should be borne in mind that the ordinary hearing is greatly in excess of what the patient needs, and hence a patient may be totally deaf in one ear and hear sufficiently well for all ordinary purposes with the other. A patient may lose half his hearing, and yet what remains will be extremely useful, and if we can keep the patient in a condition to hear moderately well, we have done much. The profounder cases may be spoken of under the head of nervous deafness; certainly the labyrinth is frequently involved. We have few post-mortem examinations to determine the exact condition of the nerve. In unfavorable cases, at first the hearing may be improved by inflation, afterward it is unaffected, they go almost unavoidably from bad to worse, especially if they take cold occasionally. Tinnitus is an unpleasant symptom to manage. Where it depends upon pressure it may be relieved by inflation and the subduing of the catarrh, which causes the whole trouble. If, however, it depends upon some anomalous condition in the labyrinth, it seems impossible to cure it unless the inflammation has given rise to exudations which press upon the terminal filaments of the acoustic nerves. Such exudation may be absorbed by the use of iodide of potassium and mercury, more especially if they are of syphilitic causation. The thickening of the lining of the tympanum and drum-membrane, accompanied by anchylosis of one or all of the bones of the ear, is a phenomenon of frequent occurrence. This of course interferes with the movements of the ossicula and membrana, and makes the ear deaf. The base of the stapes may be driven into the oval window, and held there in a condition known as impaction of its base. Sometimes we may have falling-in of the drum-membrane, accompanied with a disposition to remain sunken, and even when pressed out will fly back again. A secondary contraction of the tensor tympani I have already alluded to. It comes about in this wise: first, we have sinking of the drum-membrane, the tendon lying in a lax condition for a while; after a time it retracts so as to assume a normal state of tension; and ultimately, if an attempt is made to push the drum-membrane out, it is held by this shortened tendon. When the drum-membrane has remained sunken for a while, it seems to have adapted itself to this position with such exactness that it is always likely to remain there. You may inflate and keep it in proper position, but the minute the patient swallows and lets out the air from the tympanum, it falls back into the former position. Sometimes we find calcific plates in the drum-membrane, giving it at this point a dull, whitish appearance. This prevents the sonorous undulations from being caught and carried in successfully, on account of diminished vibratory power of the membrane. The diminution of the calibre of the Eustachian tube I have hinted at; it is usually caused by swelling of the mouth of the tube, and occasionally from real strictures, the latter being extremely rare. Another condition of the Eustachian tube which is quite serious is this: the tube may have sufficient calibre, but it will *always* remain closed in this condition. You remember that the normal state of the tube is to *be* closed, and the air is let into the tube by the opening of the tube consequent upon contraction of its muscles. Let the muscles fall into a state of atony and they fail to let air in. That is a condition quite difficult to manage.

Treatment.—The first indication in the treatment is to arrest the inflammation; the second, is the management of the Eustachian tube; the third indication is the bringing of the drum-membrane back into its proper position; the fourth is to dispose of the products of inflammation.

First, the arrest of inflammation. If there is a feeling of fulness and pain in the ear, and there are signs of hyperæmia, apply a leech every one, two, or three days, for a week or ten days. You get on badly in the treatment of this affection so long as there is much hyperæmia of the tympanum. I recently had a case treated by the family physician, the diagnosis being tubal catarrh. He had treated the tube, which improved some of the symptoms, but the hearing failed to come up. I found considerable hyperæmia of the tympanum. I think I used three leeches at intervals of three or four days, and each leech brought the hearing up perceptibly. Then I went on with merely the ordinary treatment. You may use a blister behind the ear. I should recommend this, not because I have any special faith in it, but it is an old practice, and does no harm and may do some good. The tincture of iodine on the mastoid frequently does well. I have occasionally painted nitrate of silver upon the drum-membrane with good result. This winter I have several times had pain in my own ear, and have brushed upon the drum-membrane an eighty-grain solution of nitrate of silver, which relieved the pain very nicely, producing only a moderate feeling of warmth. The tincture of iodine may be painted upon the canal near the drum-membrane, but it should be used lightly, because it may produce considerable pain. The ear should be protected from the cold, as it is sensitive and loves the warmth.

The management of inflammation of the Eustachian tube is by general treatment of catarrhal symptoms, as well as by treatment of the tube itself. I am in the habit of using a hard rubber spray-instrument which bears my name, spraying thoroughly the upper pharyngeal space, and even the nares, if necessary. Ordinarily I use a twenty-grain solution of nitrate of silver every second or third day. The solution, however, may vary from five to eighty grains per ounce, being careful that you do not cause too much pain, and that the patient reacts after the inflammation—the guide being that the parts should not remain sensitive more than a few hours after the application and relief of symptoms should be given. In the application of nitrate of silver to these parts I advise you to feel your way along somewhat experimentally, all the time observing its effects carefully. Carbolic acid to spray the throat with is an extremely good remedy, and may be used in the strength of one to two drachms to the pint of water. This hurts considerably during the first part of the application, but it does not last. A great variety of astringents may be used, but I will not stop to enumerate them here. Your remedies are a little more effective if applied directly against the mouth of the tube.

I would also advise the use of the ordinary Eustachian catheter, or my own faucial catheter. With the faucial catheter, from a fraction of a drop to two or three drops of the solution will be sufficient. With

the ordinary catheter you will require more, on account of much being arrested in the interior of the catheter. Be careful not to apply it too freely, it may excite pain, and be careful also not to throw it into the tympanum. I use my solutions pretty strong, a twenty to eighty grain solution of the nitrate of silver is quite proper to use. The indications are, to open the tube so that the patient hears as well after inflation as before. So long as you improve the hearing by inflation, you have a right to diagnosticate that there is insufficient patulency of the tube. I rarely use bougies, as true strictures are extremely infrequent.

Inflation may be accomplished by means of the Eustachian catheter, Politzer's method, by my faucial catheter, or by Valsalva's method. The objection to Politzer's method and Valsalva's is, that it inflates both ears at once, whereas we may require it in only one, although in this diseased condition generally both ears are affected. The indications for inflation are usually more than one. So long as the hearing needs to be elevated to the highest attainable point, inflate, but be extremely careful about over-inflation. I never give my patients a Politzer bag. I sometimes test the hearing by means of a watch, and if it is not quite up to the standard, then I inflate a little. You may take a flexible rubber tube and exhaust the air from the meatus externus sufficiently to draw the drum-membrane out. You may give the patient this tube, one end to be placed in the ear, and the other in the mouth of the patient, and by exhausting the air by the mouth, draw the drum-membrane outward. I object to this method somewhat, because it produces a certain amount of congestion of the tympanum. The plan has not, in my hands, been very successful. Paracentesis of the drum-membrane is often serviceable for the relief of the sunken condition of the said membrane. It is as good for the relief of tinnitus as anything I have tried. The *rationale* of its use is this: every time you make a puncture a cicatrix forms, and hence, in consequence, contraction of the membrane tends to diminish the sunken condition. It also allows the air to enter the tympanum, when the latter may somewhat represent a vacuum. To dispose of the products of inflammation, I would simply use mercury and iodide of potassium. I think I prefer to use the inunction method for four to eight days, long enough, if possible, to get a little metallic taste in the mouth—but no approach to salivation—followed by ten days or two weeks of iodide of potassium; then return to the mercury, if necessary. But you may use mixed treatment. Sometimes you will accomplish an unexpected amount by this treatment, especially if there be any syphilitic complication. Much more might be said about in this connection.

Another point I would lay stress upon—and that is, the bringing of the patient's health up to the highest state possible. Have him well fed, well clothed, and well taken care of generally, and do not let him work too hard; in short, keep the patient in the best possible hygienic condition. In summer, take baths daily if the patient bears it well; in the winter, twice per week, perhaps only a sponge-bath, followed by much friction. If clear water is depressing, use salt-water baths; artificial, if you please. A good plan is to have the patient rubbed down every night with hair mittens, or its equivalent.

METRIC SYSTEM.—The *British Medical Journal* has recently had a leader, advocating the adoption of the metric system by the medical profession in England.

Original Communications.

ON THE BRAIN OF A CHIMPANZEE.

By ANDREW J. PARKER, M.D., PH.D.,

PHILADELPHIA, PA.

By common assent of anatomists, physiologists, and philosophers, the brain has been considered as the seat of the mental processes in the higher animals. Holding as it does this dignified position, it however been regarded as the most mysterious product of nature. Within its seemingly quiet mass, protean matter assumes a new and startling phase—nature becomes conscious of herself. Everything which to man constitutes reality of existence—all thought, all knowledge, all experience—are but correlations of its changes. The reality is the felt. The felt is but a symbol for cerebral change. Nature, as an eminent thinker has remarked, must ever remain mystic to man, and never does he recognize more fully the truth of this remark than when he turns his investigations toward himself. The philosopher calculates the distance of the stars, and determines the nature of the matter of which they are composed, but when confronted with the mystery of his own consciousness he is compelled to admit his total ignorance. Naturally, therefore, that organ of the body in which these changes occur, and within whose limits these startling phenomena take place, has attracted profound attention and study, and yet, even at the present day, its intimate structure is among the least known of all the organs of the body. Indeed, it has been only within comparatively recent years that those windings and furrows of cerebral hemispheres, the so-called convolutions and fissures, have been attentively studied, and the question still remains an open one as to their exact significance. Although we may not hope to know anything of the fundamental nature of those processes, which we include under the generic term mind, yet much may be hoped for in regard to a knowledge of many of its phenomena. Already the old view—superstition it might, with propriety, be termed—that all mental phenomena are the product of a distinct and separate agent, having no dependence upon brain structure, but simply using it as an instrument in its communications with the external world, has been destroyed. It fell with the fall of the old metaphysical school. It fell as the science of biology evolved. It now takes rank with the exploded notion of a vital force. In its place has been substituted the doctrine that all the phenomena of life depend upon the elements of life—namely, the organic cells. The sum total of the life of an animal is the summation and resultant of the action of its individual parts or cells. Hence, mental phenomena must arise from the action of certain definite cells, and the mental life of a man, as of an animal, equals the sum of the actions of these cells. Because the method or way in which this is accomplished is not understood, is no reason for rejecting what reason, experience, and observation force upon us. Although the conversion of the forces of matter—modes of motion—into consciousness and thought, must forever remain inscrutable, yet the fact remains. Experience is our sole teacher, and the constant conjunction and relation of phenomena is our sole ground for affirming a necessary connection between them.

The consciousness of matter must be admitted and recognized for the same reason that we admit it to possess any of its other properties. We affirm that a muscle contracts, because of the nature and position of its molecules; so must we affirm that a brain thinks, because of the nature and position of its molecules.

Recognizing this fact, it forces upon us the conclusion that the form and structure of the brain must be correlative with its mentality, and therefore that in brains in which the structures closely resemble each other we will find a corresponding similarity in the mental processes. At present the field of comparative anatomy is being eagerly explored, and observations upon the brains of animals, and especially of those most nearly related to man, are justly regarded as of considerable importance.

The order of *Primates*, to which man belongs, is divided into three groups: the *Lemuridæ*, or lemurs; the *Simiadæ*, or monkeys and apes; and the *Anthropidæ*, including the various races of men.

The chimpanzee (*Troglodytes niger*) belongs to a division of the *Simiadæ*, known under the name of the *Anthropomorphæ*, or man-like apes. This division includes three genera: *Hylobates* (gibbons), *Pithecus* (orang), and *Troglodytes* (chimpanzee and gorilla). From their near genetic relations to man, observations on the brain of these animals are of especial interest and importance. The following brief account is given in the hope that it will prove of interest to the readers of the MEDICAL RECORD. A more detailed description will be read before the Philadelphia Academy of Natural Sciences.

The body of the chimpanzee, the description of whose brain is here given, was kindly placed in my possession by Prof. Leidy. It is that of a young male of about four years of age, which died in the Zoölogical Garden of Philadelphia last winter. The cause of death appeared to be gastro-enteritis. Otherwise the animal was in good condition. The brain was in an excellent state of preservation, and on being removed from the skull, was placed in a solution of chloride of zinc of sufficient specific gravity to float it. It was afterward transferred to alcohol. Its condition is therefore very perfect, there being little distortion or change in the relative position of its different parts.

The length of the animal, from the vertex to the heel, measured two feet and four inches; vertex to tuberosities of the ischium, one foot six inches; circumference of the head, fourteen inches; distance over the vertex from one external auditory meatus to the other, five and three-fourths inches.

The animal weighed, while living, according to Mr. Arthur E. Brown, Superintendent of the Zoölogical Garden, eighteen pounds.

The entire brain weighed 9¾ oz., about half an ounce less than the brain of a female chimpanzee which died at about the same time, and which weighed, according to Dr. H. C. Chapman (Proceedings Academy of Natural Sciences, Philadelphia, 1879), 10 oz. 10 grs. According to Owen, a half-grown male's brain weighed 9¾ oz., and that of an adult female chimpanzee, 13¾ oz. A specimen examined by Marshall weighed 14 oz., and one by Traill 11 oz.

Dr. H. C. Chapman, in the paper referred to above, states, that on examining the brain before removal, he found the cerebellum uncovered by the posterior lobes of the cerebrum to the extent represented in the plate which accompanies his paper. As so much discussion has taken place in reference to this question, and as Dr. Chapman's observation is not in accordance with the most recent views on this subject, I examined the brain in my possession very carefully, and found that the cerebellum was completely covered by the cerebrum. A plaster cast was then made of the interior of the cranial cavity, and the posterior lobes were found to project back of the cerebellum four mm. As Dr. Chapman's plates of the brain of the chimpanzee show that his specimen has undergone considerable distortion and flattening, and plainly indicate that the cerebrum has fallen forward and the cerebellum been pushed backward, and that therefore, in the natural condition, the cerebellum would not be uncovered, at least to the extent represented by the plates, I thought it would be desirable to make a cast of the cranial cavity in Dr. Chapman's specimen, in order to be able to compare it with the cast referred to above. Having obtained this, however, I found that in this case, also, the posterior lobes of the cerebrum completely covered the cerebellum and projected beyond them to the extent of 3 mm. Dr. Chapman's observation must therefore have been influenced by this distortion; and that such a mistake might easily occur is supported by the opinion of Marshall (Brain of Chimpanzee: Nat. History Review, 1861), who remarks as follows: "Such a deformation must occur to a greater or less extent in every brain removed from its cranial case and placed in a similar position. Its effects are surprising to those who are not familiar with them, and cannot be correctly estimated without comparing the so-altered brain with a cast of the interior of the cranial cavity. It influences the form of the encephalic mass in all three of its cubical dimensions. The general results are: a slight lateral bulging of the cerebral hemispheres opposite the parts tied together by the corpus callosum; a more marked falling asunder of the hemispheres at each extremity, but especially behind; a moderate elongation of the hemispheres; and lastly, a very marked compensating flattening on both the upper and under surfaces, but especially on the former, so that its characteristic convexity is completely lost. Moreover, the cerebellum, together with the pons and medulla oblongata, drag on the cerebral peduncles, so as to make these latter assume a position nearly parallel to the under surface of the brain, instead of descending obliquely from it; hence the cerebellum falls backward farther than in its natural state, presses somewhat aside the posterior ends of the cerebral hemispheres, and so modifies the proper relative position of these parts of the encephalon. A comparison must be referred to a cranial cast, or the brain must be hardened in the cavity of the skull."

I have since made casts of the cranial cavities of several skulls of gorillas, chimpanzees, orangs, and in all thus far examined have found the cerebellum to be completely covered by the posterior cerebral lobes.

According to Macartney, Gratiolet, Thomson, Huxley, Rolleston, Marshall, Spitzka, etc., and in three cranial casts of chimpanzees by the writer, the cerebellum is completely covered by the cerebrum. On the other side we have the assertions of Owen, the figures given by Tyson, Tiedemann, Schroeder van der Kolk, and Vrolik, and the observation of Dr. Chapman. Owen's assertions have been proved, through the researches of Huxley, Flower, etc., to be incorrect. Tyson's figures are very imperfect, and so much distorted as to render them useless. In Tiedemann's figures, although they are carefully drawn, the vertex shows evident signs of flattening, the orbital surfaces have lost their

characteristic concavity the hemispheres have fallen somewhat forward and apart, so that the backward projection of the cerebellum is not to be considered as the natural position when within the cranial cavity. The same objections apply even more forcibly to the figures given by Schroeder, van der Kolk and Vrolik, and the enormous surface of the cerebellum left uncovered shows clearly that in reference to this point these plates are very imperfect. As Dr Chapman's observation does not agree with the facts, as shown by a cranial cast, it must be considered as due to the same cause—that is, the change in relative position which takes place when the membranes of the brain have been removed, or the brain itself removed from the cranial cavity. Observations up to the present time would therefore seem to show that in the chimpanzee the cerebellum is completely covered by the posterior cerebral lobes.

General Form, etc.—The brain, when viewed from above, is ovoid in shape, the narrowest end of the oval being situated anteriorly. On comparison with the human brain, we find the chief difference consists in the greater length and more equal width of the frontal region in man. In a profile view, the brain presents above a globular form, the upper border of the hemisphere following a regular curve, the vertex or highest point of which is situated about midway between the anterior and posterior parts of the brain.

The frontal lobe is quite large, but has little vertical height, and terminates anteriorly in a beak-like projection, between which and the temporal lobe we have the strongly arched concave orbital surface, which is so characteristic of both the orang and chimpanzee when compared with the flattened surface of the same region in man. The parietal lobes are quite large. The temporals are well developed, and project markedly downward. As to the posterior or occipital lobe, it is large, possessing considerable vertical height, and projects completely behind the cerebellum. The inferior border of the hemisphere, extending from the occipital to the end of the temporal lobe, is arched, with its convexity upward instead of pursuing a horizontal and nearly straight direction, as it does in man. The lateral surfaces of the hemisphere are evenly convex, and not wall-sided, as found in the orang by Rolleston.

On a basal view, the pointed character of the frontal lobes anteriorly is very marked. A median ridge, equal in height to the downward projection of the temporal lobe, extends on each side of the longitudinal fissure, and bounds the extremely concave orbital surfaces internally. The cerebellum is flatter and proportionately wider than in man.

Fissures and Convolutions.—The fissure of Sylvius has the same relations as in man, but pursues a more vertical direction. It consists, as in man, of an ascending and a horizontal branch. The fissura centralis, or fissure of Rolando, is situated more anteriorly than in man, and is undulating in its course, presenting three or four well-marked curves. In man nearly one-half of the upper cerebral surface lies in front of this fissure, while in the chimpanzee only about one-third is found situated in front of it. The parieto-occipital internal perpendicular fissure on the left hemisphere is continuous with a well-marked external perpendicular fissure, but on the right side is separated completely by a well developed *pli de passage supérieur externe*. On the left side, therefore, the posterior border of this fissure, the operculum of Giratiolet, is smooth and uninterrupted, as we find it in the lower primates, while on the right side it is bridged over as in man.

Convolutions and Fissures of Frontal Lobe.—In the frontal lobe of the chimpanzee we find the same fissures and convolutions as in man. A gyrus centralis anterior bounds the central fissure in front and arches around the two ends of this fissure to join the posterior central convolution above and below. From this convolution there passes forward three frontal convolutions—a superior, middle, and inferior, separated by two fissures—the superior and inferior frontal fissures. A well marked fissura præcentralis exists, which on the left side is continuous superficially with the ascending branch of the Sylvian, but is perfectly distinct from it on the right. The gyrus frontalis superior arises by a single root from the anterior central convolution, is wider than the middle and inferior, and is marked by a number of secondary fissures. The gyrus frontalis medius arises on each side by a distinct root from the anterior central convolution, is very tortuous, and but slightly marked by secondary fissures. The gyrus frontalis inferior also arises on the right side by a distinct root from the gyrus centralis anterior, but on the left side is separated from it by the fissura præcentralis. On the orbital surface, besides the sulcus olfactorius we have a well-marked sulcus orbitalis, which has the same triradiate arrangement as in man.

Convolutions and Fissures of the Parietal Lobe.—In the parietal lobe there is a distinct and well-marked fissura interparietalis, which extends back to join the external perpendicular. On the left side its continuity is interrupted by a single bridging convolution; while on the right, although tortuous, it is represented by a single continuous furrow. In front of this fissure, and between it and the central, is a well-marked gyrus centralis posterior, which at its upper extremity passes into the mesial surface and forms a distinct lobulus præcuneus as in man. Beneath this fissure is the gyrus parietalis inferior, which is divided into an anterior portion, or lobulus supramarginalis, and a posterior or gyrus angularis, which have the same relations as in man.

Convolutions and Fissures of the Occipital Lobe.—The occipital lobe is sharply marked off above from the parietal lobe by the external and internal perpendicular fissures, their continuity being broken, however, on the right side by the superior external *pli de passage*. Inferiorly, it passes directly into the temporal lobe as in man. It presents on its external or lateral surface a strongly marked triradiate sulcus, which divides it into an anterior superior, an anterior inferior, and a posterior lobule, which correspond with the three convolutions found on the same surface in man. On the mesial surface there is a well-developed lobulus cuneus, from the apex of which there passes forward on both sides a well-developed gyrus cunei (internal inferior *pli de passage*) to join the lobulus præcuneus. This convolution completely separates the parieto-occipital fissure (fissura perpendicularis interna) from the calcanic fissure, whilst in man this convolution is but feebly, if at all, developed, and the parieto-occipital and calcanic fissures join each other. The fissura calcarina presents the same appearance as in man, except that anteriorly through the slight development of the gyrus dentatus it passes superficially into the hippocampal sulcus of the temporal lobe. Beneath the calcanic we have a well-developed fissura collateralis separating a well-developed lobulus lingualis from the lobulus fusiformis.

The convolutions and fissures of the mesial portion

of the fronto-parietal lobe and of the temporal lobe differ but slightly from the same structures as found in the brain of man.

The lobulus centralis, or island of Reil, is well developed, and is marked by several conspicuous radiating convolutions (gyri breves, Gall), and lies entirely concealed beneath a well-developed operculum.

From the above short description it may be seen that every fissure and convolution of the human brain is well represented in the chimpanzee's brain, so that we must expect and find, according to the observations of recent observers, that in many respects the mental processes of this animal resemble those found in the lower races of mankind.

ON SOME POINTS IN THE THERAPY OF CHLORAL HYDRATE.

By J. W. HICKMAN, M.D.,

DELTA, PA.

My object, in these notes, will be not so much to present new matter in the therapeutics of chloral as to give a bird's-eye view of the present state of our knowledge, as recorded in the literature of our day and as verified in my own experience.

Although known to the chemical world since 1832, chloral was not recognized to possess therapeutic worth till in May, 1869, when Oscar Liebreich, of Prussia, announced * that important truth, attested by a well-executed set of experiments.

So far very little of our knowledge of the uses of chloral has been derived from its physiological action; scientific therapeutics has added but a trifling quota to the fund of ascertained facts relative to its practical application in disease. Notwithstanding this, however, we know a great deal of its correct use and much of those conditions contraindicating its administration. For instance, no practitioner who keeps apace with the progress of the day would, for a moment, think of exhibiting chloral where either the respiration or circulation were seriously compromised. It would be absolutely criminal to give it in advanced (or recent, either, for that matter) disease of the lungs where the right heart is being continually overtaxed. Nor would he be less guilty who would think of giving chloral in the sleeplessness of valvular disease of the heart. Yet it has been but a few weeks since I knew a practitioner of a neighboring city to suggest the use of this very drug in precisely such a case as the last-named, with a severe dyspnœa superadded. At this point I must relate a most instructive case recorded by Fothergill †: "A patient was taken into the West London Hospital, with emphysema and aortic stenosis. In spite of rest, digitalis, and ammonia, he was liable to attacks of dyspnœa, which had come on *since* his admission into hospital. On searching for an explanation, it was found that the house-surgeon had benevolently prescribed chloral for the sleeplessness complained of. This was at once stopped, and the attacks of dyspnœa never returned, though the man gradually sank." After the principle enunciated above, it seems idle to remark that a fatty heart would not certainly brook even a medium dose of chloral; in such cases paralysis of the heart has occurred before the involvement of the lower centres of the brain. J. Crichton Browne has made a curious observation, and one of no small practical importance. He has ascertained that chloral exerts an effect proportional to cerebral development; that it must be administered most cautiously to the most intellectual. This fact is further borne out in that it takes a larger than ordinary dose of chloral to induce its physiological effects in microcephalic idiots. I have seen this latter point abundantly evidenced. This may, perhaps, go to explain some instances of death occurring from a moderate dose—fifteen to twenty-five grains. Again, the matter of bodily temperature should have much to do in determining the proper dose of chloral, for serious symptoms, and even death, have occurred from undue neglect of this consideration. Even so apparently trivial a point as the temperature of the patient's room should be taken into account; for we must remember that the tendency of this agent, besides slowing the action of the heart, is to dilate the peripheral vessels, and thus to increase the heat-losing area of the body. Thus we see that great circumspection should be used in prescribing a remedy of such varying potency as chloral. This care should be taken, not only to avoid death, but that we may derive the most satisfactory and beneficial results from its use.

Standing forth most prominently in the therapeutics of chloral is its value as a sleep-producing agent. The late Prof. Biddle says: * "It is a most reliable hypnotic, second only in this particular to opium." Now, from the view of this eminent teacher, the writer feels in duty bound to dissent. It should be recognized as an undisputed fact that there is no soporific agent at all comparable to chloral. Varied in dose, according to rules above laid down, it least frequently disappoints the expectations of the practitioner. It does not induce the swimmy, broken sleep of opium, but quiet, dreamless, and refreshing slumber, strikingly resembling that of health. The patient may be awakened with a confidence that he will at once relapse into forgetfulness. Nor is it, like opium, followed by disagreeable sequences, either cerebral or gastric. On the contrary, so far as the stomach is concerned, digestion is not unfrequently stimulated by its use. It will not, however, exert the slightest soporific influence in painful conditions of the system—it possesses no anodyne properties whatever. When the object is to lull pain and induce sleep, about one-fourth of a grain of morphia sulph. with ten grains of hydrate of chloral will be found a most valuable combination.

Then, too, in conditions of the system where the patient is *too weak to sleep*, anodynes will be found to aggravate rather than secure rest; while in chloral, perhaps, with the bromides given with a little light wine or champagne, we have the most efficient means at our command.

In the sleeplessness due to excessive mental work, chloral exercises a peculiarly happy influence, as the writer has fully verified in his own case while yet a student. When pushed almost to the extreme of nervous and mental exhaustion from this cause, chloral would induce a night of refreshing sleep with an entire renewal of the jaded energies.

Chloral is one of the agents that has seemed to be of service in tetanus. Macnamara lays great stress upon its value, and announces that of twenty cases in India, all traumatic, seventeen recovered by the use of chloral. In large doses it is, perhaps, as effective as any drug we possess. Prof. Gross very ac-

* Das Chloralhydrat, ein neues Hypnoticum und Anæstheticum, und dessen Anwendung in der Medicin. Zweite Auflage. Berlin.

† Antagonism of Medicines, p. 53.

* Mat. Medica.

curately expresses the truth, however, when, in summing up the internal treatment of tetanus, he says: "All drugs are, in fact, equally of apocryphal virtue."

In the management of sea-sickness no agent has given such satisfactory results as chloral. The usual dose of about twenty grains is to be given every three or four hours, the patient observing the recumbent posture and taking nourishment in some shape or other.

Bartholow bears personal testimony that there is no remedy now known so efficient in cholera as chloral hypodermically used. The same treatment is also peculiarly effective in cholera morbus. In both conditions the remedy is enhanced in value when combined with a little morphia, as follows: ℞ Chloral hydratis, ℥ij; morph. sulph., gr. iv; aquæ laurocerasi, ʒij. Misce. Sig. From fifteen to thirty minims hypodermically. This injection produces considerable burning pain, and sometimes an indurated lump, but is rarely, if ever, followed by suppuration.

In an extract in *The Practitioner* for October, 1879, Dr. Curci states that chloral is a most valuable remedy in dysentery. It may be given either by mouth or rectum. When given by the mouth it was found advantageous to anticipate its use by a slight purgative. He is very emphatic in his praise of the remedy, and, judging from its effects upon like lesions on the exterior of the body, together with its ascertained systemic effects, I would strongly advise that the profession give it a trial.

Again, Dr. J. H. Scorff reports four cases† where he was successful in removing the vomiting of pregnancy by rectal injections of twenty grains, night and morning. He only found it necessary, in the cases recorded, to administer the remedy three or four times. This also merits remembrance and repetition at our hands.

Chloral is the remedy *par excellence* in the ravings of delirium tremens. Like other drugs, it sometimes deceives us, but in general will be found reliable. Care must be taken in old debauchees that the dose given be not excessive; especially must we be circumspect where there is reason to believe the circulatory system has undergone degeneration of tissue, or rest may be induced which knows no reaction.

Chloral will also be found highly serviceable in certain other conditions of the system attended with delirium and insomnia combined.

It has been recommended and used in puerperal convulsions; but in my opinion is to be absolutely and radically condemned as a *sole remedy*. Too often already has it lulled the physician and friends of the patient into a deceitful security to be trusted further. If there is a truth in the whole domain of medicine, the lancet boldly used is *the one and only reliable* agent in this condition.

On the contrary, infantile convulsions may frequently be suspended by the discreet use of chloral.

Attacks of laryngismus stridulus are speedily broken up by timely doses of chloral.

Its use has been urged in whooping-cough, but its value is extremely questionable.

Exceptionally good results are obtained in inflammatory and febrile conditions when attended by delirium and wakefulness, with a high temperature. Recently, in a case of typho-malarial fever treated by the writer, chloral was found to control, in a most happy manner, the busy, exhausting delirium attendant thereon. It was administered by enema, and the sleep induced constituted the turning-point in the case.

MEDICINAL SPRING WATERS.

By JOHN C. PETERS, M.D.,

NEW YORK.

As analysis of mineral waters, it is said, shows that the important minerals present in medicinal springs, either form integral parts of our bodies, or their presence is occasionally necessary to the accomplishment of some of the vital processes; but they may easily be imitated by artificial prescriptions.

We will first consider the *chlor-sodic*, or common table-salt waters, all of which, like the *Saratoga*, are tonic and stimulant, and finally aperient. Saratoga water contains 390 grains of muriate of soda to the gallon, 131 grains of bicarbonate of lime, 54 of bicarbonate of magnesia, 34 of bicarbonate of soda, and 409 grains of carbonic acid gas. These waters give activity to the cutaneous, intestinal, and urinary functions, developing appetite, and demanding a substantial diet during their use. They are also powerfully alterative.

The High Rock waters are recommended in dyspepsia, cutaneous diseases, hypochondriasis, urinary and hepatic calculi, and biliousness. Astonishingly large calculi, together with great quantities of gravel, are often worked away by these mineral waters, and patients are often seen exhibiting them to their friends and acquaintances.

The *sulph-sodic*, or Glauber salt waters, like those of *Carlsbad* in Bohemia, and Hunyadi, are much less common than the chlor-sodic; and even in the strongest of them there is often much less sulphate of soda, in proportion, than there is muriate of soda. Carlsbad contains 45 grains of solids in 16 ounces; of these, 20 are sulphate of soda; 9, carbonate of soda; 8, chloride of sodium; with 8 cubic inches of carbonic acid gas. The Bavarian *Kissingen* waters, which are often erroneously included in this class, have 65 grains of solids in 16 ounces, of which 45 are chloride of sodium; 8, carbonate of lime; and 4, sulphate of magnesia; with 41 inches of carbonic acid gas. Glauber salt extracts a much larger amount of water from the blood than the chloride, and hence is much more purgative—in fact, the most of it is discharged with the fæces; hence, very little is absorbed into the blood, or reaches the kidneys, or gets into the urine. Sulphate of soda in mineral waters is generally associated with carbonate of soda, much free carbonic acid, iron, muriate of soda, etc. The two latter ingredients counteract the tendency of the others to debilitate by depletion and refrigeration. The carbonate and chloride of sodium of these waters reach the urine, which becomes increased in quantity and is rendered alkaline. The blood is depurated, and should be resupplied with healthy materials; the appetite is improved and digestion promoted. The cases most benefited by the *Carlsbad* waters are liver and abdominal diseases, gouty and rheumatic disorders, dyspepsia and constipation, while persons with enlarged livers derive remarkable relief. The *Kissingen* waters are valuable in habitual constipation, congestion of the liver and kidneys, dyspeptic eructations or flatulence, and in disease of the mesenteric glands. Almost all the benefits of these waters may be obtained by poor people, by a mixture either of Glauber salts, or Epsom salts, or both, with a little table salt, in water.

Where sulphate of lime replaces the sodic salt the waters are sedative, alterative, and antispasmodic.

The *alkaline sodic waters*, rich in carbonate of soda,

are well represented by the *Vichy* waters of Central France. Bicarbonate of soda and carbonic acid gas form the predominating ingredients, each 16 ounces containing from 36 to 39 grains of carbonate of soda, and from 6 to 20 grains of carbonic acid gas. Wherever the use of strongly alkaline waters are indicated, those of Vichy will prove useful. The diseases which derive most benefit from them are pulmonary catarrh, debility and irritability of the digestive organs, chronic enlargement of the liver and spleen, uric acid gravel and calculi, chronic gout and rheumatism, and some cases of albuminuria, especially in the fatty kidney. Obesity has been lessened by these waters, and they have been used when the blood contains an excess of fibrin. The dose is from one-half to two pints daily—and poor people may readily imitate them by putting rather more than half a teaspoonful of soda in a pint of warm water, or in ice-water. Three of the Vichy springs are thermal, having a temperature from 105° to 110° Fahrenheit; while three are cool, varying from 53° to 80°.

The *alkaline chlor-sodic* waters, like those of *Ems* in the Duchy of Nassau, are weaker than those of Vichy. The waters are alkaline, saline, and gaseous. The chief constituents are bicarbonate of soda, chloride of sodium, and bicarbonate of magnesia. These waters are generally recommended in bronchial and pulmonary affections, and in the dyspepsia of those who have a tendency to phthisis. But able physicians, such as Carus, of Dresden, prefer the waters of *Soden*, in Nassau, for consumptive cases, although the principal constituent of these waters is merely chloride of sodium. This is only one form of the alkaline treatment of consumption. It is well known that one of the Ems springs is in repute for the cure of sterility, especially in fat women, and in those who have fatty degeneration of the ovaries, etc.

Many authors divide the *sulphur waters* into the *sodic* and *calcic*, and say that the former are frequently devoid of the smell of free sulphuretted hydrogen, and are often more powerfully remedial than the malodorous calcic waters, such as Sharon and Richfield, quite contrary to the popular notions on the subject. Cutaneous, rheumatic, neuralgic, and catarrhal disorders are those most commonly treated by sulphur waters, although gunshot wounds and abscesses heal very quickly under their use.

The *chalybeate or ferruginous* waters are divided into those which contain much carbonic acid gas, like those of Schwalbach, Spa, Pyrmont, etc.

The *Schwalbach* waters of Nassau, near Wiesbaden, owe their invigorating properties to carbonate of iron, which is held in solution by an excess of carbonic acid. They also contain a little soda, magnesia, and lime. The Weinbrunnen contains most iron, and is believed to counteract the evils arising from the excessive use of wine. The Paulinenbrunnen is used for torpid livers, and its waters are drunk fasting to the extent of one to three glasses, and are highly recommended in cases of impaired strength.

The *Spa* waters of Belgium are largely charged with carbonic acid, their chief constituents being the bicarbonates of soda, iron, lime, and magnesia. They are taken to the extent of two or three pints daily, and impart power, strengthen the digestion, and are valuable in cachectic diseases.

The *Pyrmont* waters are saline, earthy, and chalybeate.

The *Baden-Baden* waters are still weaker, having only about 23 grains of salts to the 16 ounces, of which 18 grains are chloride of sodium; 2½ grains are sulphate of lime; only one-tenth grain of iron, with less than half a cubic inch of carbonic acid. The temperature is from 117° to 154° Fahr., and the waters are of course transparent, inodorous, and slightly saltish, and their efficacy must be slight.

The *Homburg* waters are stronger, containing about 110 grains of salts in the 16 ounces, and are highly charged with 48 cubic inches of carbonic acid. The chief salts are chloride of sodium, 79 grains; chlorides of magnesium and calcium, 15 grains; carbonate of lime, 11 grains, and the same of iron. The Kaiserquelle has more chloride of sodium than the favorite Elizabethquelle—viz., 117 grains; more chloride of calcium, and more iron. The Stahlquelle is more ferruginous than either. The flavor of all these waters is refreshing, saltish, somewhat bitter, and chalybeate. Gout, dyspepsia, strumous enlargements of glands, debility of the reproductive organs, constipation and hypochondriasis have been benefited by them. From two to four tumblerfuls are taken fasting.

The *saline purgative waters* have sulphate of soda or magnesia, or both, as their chief ingredients. The principal ones are Epsom, Cheltenham, Leamington, Seidlitz, Pullna, Carlsbad, Marienbad, and Hunyadi.

The *Cheltenham* waters contain chiefly the chlorides of sodium, calcium, magnesium, and sulphate of soda. They are but slightly gaseous. They enjoy considerable reputation in bilious and liver diseases engendered in hot climates, in gouty and rheumatic disorders, in the lithic acid diathesis, in plethoric and irritable states of the system, in skin diseases, in dyspepsia with constipation, as well as in some forms of amenorrhœa and chlorosis. The dose is from one-half to one pint before breakfast.

The *Leamington* waters in Warwickshire also contain the chlorides of sodium, calcium, and magnesium, with sulphate of soda. The chief gas is carbonic acid, with great quantities of oxygen and nitrogen. Their action is aperient and alterative, and being more active than the Cheltenham, they agree better with invalids of a torpid rather than of an irritable temperament.

The *Pullna* waters of Bohemia are bitter, saline, very nauseous, and indigestible, and possess no advantages over the common purgative salts, viz., Epsom and Glauber. They contain 124 grains of sulphate of soda (Glauber salts) in 16 ounces; 93 of sulphate of magnesia (Epsom salts); 16 of chloride of magnesium; and 6 of carbonate of magnesia.

The *Marienbad* waters of Bohemia are saline chalybeate, the chief constituent being sulphate of soda, with a moderate quantity of iron and carbonic acid. They are laxative, alterative, and tonic in proportion to the dose—from one to six tumblerfuls; while they increase the action of the liver and kidneys, and promote appetite. They are particularly valuable in chronic disorders of the abdominal viscera. The mud-baths are said to heal chronic ulcers and disperse glandular swellings. The gas-baths, containing carbonic acid with a small amount of sulphuretted hydrogen, soothe muscular and neuralgic pains, and remove torpor of the female organs.

The *Iodobromated* waters of *Kreutznach*, in Rhenish Prussia, are the most celebrated. They are rather nauseous and bitter, but have a considerable reputation in the cure of uterine diseases and scrofulous affections. They contain about 90 grains of salts in 16 ounces of water, of which 73 are chloride of sodium, 13 chloride of calcium, 4 chloride of magnesium, ½ grain of bromide of magnesium, and a trace

of cubic feet. They have proved valuable in connection with the uterine organs in hypertrophy and indurations of these parts, and in deficient secretion of the mucous. Although they will not absorb true fibroid tumors, they relieve oedema and congestion of these growths.

The *Bedford Baths* waters contain a little chloride of lithium.*

[To be continued.]

A MODIFICATION OF THE OPERATION FOR FISTULA IN ANO.

By J. J. KNOTT, M.D.,

ATLANTA, GA.

The following procedure will be found to do away with some of the inconveniences, and the most of the pain attending the operation for fistula in ano. I have tried it in two cases with perfect satisfaction. Introduce the anal speculum, with the fenestra on a line with the fistulous track, pass the director through the fistula, allowing the speculum to remain *in situ*. With your curved, sharp pointed bistoury, divide the tissues, and withdraw the speculum, director, and knife all together. You get the following advantages by this method: avoidance of pain to a great extent; a full view of all the parts; and, so far in my hands, the avoidance of tenesmus of the rectum, which is likely to bring on strangury and retention of urine. The two cases in which this method was adopted were of a nervous temperament—cases which would call for an anæsthetic to allay pain consequent on the operation by other methods.

Reports of Hospitals.

ST. THOMAS'S HOSPITAL, LONDON.

A Case of Ulcerative Endocarditis after Rheumatic Fever.

(Reported by A. Clifford Mercer, M.D., Clinical Clerk.)

Comments on the Case by Dr. Bristowe.

Alice H——, aged thirteen years, was admitted into St. Thomas's Hospital, under Dr. Bristowe, April 8, 1879. Her father had suffered from rheumatism, and she herself, five years before, had had two somewhat severe attacks of rheumatic fever, from which, however, her friends believed she had completely recovered. But in February of this year she began to have, when she overexerted herself, dyspnœa and palpitation, which probably were dependent on some rheumatic lesion in her heart.

The illness for which she was admitted into the hospital was her third attack of rheumatic fever, which had begun six weeks previously. The joint-inflammation had first appeared in the knees and ankles, and had then subsided only to appear again in the right knee, and later in the left wrist.

On admission, she was pale, her cheeks were slightly flushed, and she complained of pain in her right knee and left wrist. These joints were red, swollen, and tender. She also suffered from palpitation and dyspnœa, increased by exertion, but from no cardiac pain. The heart's impulse was diffused, but the apex seemed to beat one inch below and one inch external to the left nipple. From this point the precordial dulness extended two inches and a half to the right to the left border of the sternum, and upward to the upper border of the third rib. At the apex was felt a well marked thrill, which was chiefly systolic, but also slightly presystolic. A loud, blowing systolic murmur was heard at the apex, in left axilla, and at the angle of the left scapula. No presystolic murmur could be heard. There was no murmur at the base of the heart nor œdema of the legs. The pulse was 96, regular, soft, and compressible. The remaining organs of the chest and abdomen were examined and found to be natural. The tongue was moist, coated white, the appetite fair, the bowels costive; the urine natural; the temperature 97.4 Fahr., and there was no thirst nor vomiting. In the evening her temperature went up to 102.6 Fahr.

April 9.—She was ordered sod. salicyl., gr. xv.; syrup aurant., ℥ i., aquæ ℥ i., every four hours, milk diet, and beef tea. Her temperature became highest at midnight, when it was 102.6° Fahr.

April 10.—The pain and swelling had disappeared from both the knee and wrist. The temperature reached 102° Fahr. at midnight.

April 14.—Since the 10th there had been a nightly rise of temperature, but no return of joint symptoms. The sod. salicyl. was discontinued, an ounce of quinine mixture† ordered three times a day, and fish added to her diet. Her respirations were 24, and her pulse 132.

April 16.—Haust. sennæ comp. opened the bowels.

April 17.—The febrile temperature had continued, and in the evening it reached 103.4° Fahr. Pain and swelling appeared in the left wrist and right ankle. Sod. salicyl. was ordered again.

April 18.—The temperature was still up, but the pain and swelling disappeared.

April 22.—The temperature had continued high. The urine showed a trace of albumen.

April 25.—There had been a trace of albumen in the urine for several days. Over the apex of the heart was heard a loud, rasping, systolic murmur, and the second sound was not distinguished. Over the left base was heard a loud, rough systolic murmur, made louder by pressure with the stethoscope. The second sound at the base was loud and abrupt. The dulness had increased to the right to the mid-sternal line. The thrill continued without change.

May 2.—The urine contained a trace of albumen.

May 5.—For a day or two the temperature had been nearly normal. Sod. salicyl. was discontinued, and tr. ferr. perchlor., ℥ x.; tr. digital., ℥ v.; infus. quass., ℥ i., were ordered three times a day.

May 6.—She had slight œdema in both feet. The urine contained a twentieth of albumen. She was ordered ferr. et quin. citrat., gr. v.; ex aquæ, t. d. s.; and wine, ℥ ij.

May 20.—For weeks the temperature had been too high by from one to four degrees Fahr., being highest at irregular hours from day to day.

June 6.—The irregular febrile temperature had continued. The patient had become more and more quiet, and was drowsy. The pupils were dilated. She had no pain, no swelling nor rigors. The splenic dulness measured in the axillary line four inches, and extended too far forward. The lower edge of the spleen, on deep inspiration, was felt below the ribs, but it was not tender. The heart-signs remained the same.

* The above is a very fair specimen of the ordinary way of writing about mineral waters.

* Milk diet, St. Thomas's Hospital, consists daily of 12 oz. of bread, ¾ oz. of butter, 1½ pt. of milk, 8 oz. of rice or bread pudding, ¾ pt. of tea, with milk and sugar for breakfast, and ¾ pt. of tea with milk and sugar for tea.

† Mist. quin., St. Thomas's Hospital: quin. sulphat., gr. i.; acid. sulphuric. dil., ℥ ij.; tr. cardamom. comp., ℥ ss.; aquæ destillat., ℥ j.

June 12 and June 18.—She continued to be in the same condition.

June 28.—During the previous night she had often waked and cried with pain in her left side. The splenic dulness remained the same, but the organ was now tender. She continued drowsy—indeed, became very drowsy, the heart-signs remained the same, and the irregular rises in the temperature continued. She was becoming thin, having gradually emaciated since her admission.

The diagnosis had been and still was, rheumatic fever followed by ulcerative endocarditis (involving the mitral valve), with emboli from the heart, in different parts of the body, but especially in the kidney and spleen.

July 14.—For two days she had passed her motions and urine in bed. About 11 A.M. she was noticed to be paralyzed throughout her right side, and to have aphasia. She could not move the right arm or leg. The right eye closed imperfectly. The mouth was drawn to the left, and the tongue protruded to the right. Swallowing was difficult, and she could only whine in answer to questions, though she occasionally seemed to say "no." She saw with both eyes. The pupils were equal and contracted to light.

July 16.—The right arm was slightly better, and to some extent resisted being moved. The right leg was stiff and somewhat flexed. The left arm was tremulous, and she picked at the bedclothes and her lips with her left fingers. The left knee was kept flexed and in constant motion by flexion of the thigh on the abdomen. It was slightly red and swollen, and seemed painful. The aphasia and dysphagia were about the same. She once fairly said "milk," and was only able to swallow a very little wine and nourishment, although she was hungry. She recognized her mother. The pupils were equal, respirations 44, and the pulse 148.

July 17.—There was less motion in the left knee. She became weaker. The respirations were 40, and the pulse 156.

July 18.—The paralytic symptoms remained the same. She sweated, but had no rigors, and appeared moribund. The urine, drawn off by a catheter, had a sp. gr. of 1032, was thick, yellow, and contained copious lithates and much albumen. Since the 14th her temperature had been gradually going up from 101.2° Fahr. to 106.6° Fahr. She died at 7.45 P.M.

July 19.—A *post-mortem* examination was made, when such organs as were involved appeared as follows:

The lungs were œdematous, but otherwise natural.

The pericardium contained four ounces of serous fluid. There was no evidence of pericarditis. The heart weighed nine ounces. Its general appearance was natural. The left ventricle was hypertrophied. The aortic valves were quite healthy. The mitral valve was also for the most part healthy, but its edges here and there had small pendulous excrescences which were broader at their free than at their attached extremity. These had a finely granular, wart-like appearance, and were covered with recent red clot. The internal surface of the left auricle, over a space about the size of a silver half-dollar, was covered with a finely granular and reticulated false membrane, which, after being easily scraped off, left the endocardium thickly covered with minute elevations, which contrasted strongly with the natural smoothness of the rest of the auricular endocardium.

The kidneys weighed seven ounces and a half. The capsules were somewhat adherent, especially here and there over depressions, beneath which were found contracting infarcts. In other places beneath the surface were hard nodules, which on section proved to be conical, more recent infarcts. There were also a considerable number of infarcts scattered through the substance of the kidneys.

The spleen was enlarged and weighed seven ounces. Before it was removed its lower margin extended an inch below the costal arch. It had several large infarcts, one being about an inch and a half in diameter.

The liver on the surface of the right lobe presented a deeply colored area, in extent about two or three square inches, and which extended into the organ about an inch, where it was limited by a wavy, clearly defined border. Apart from the deep coloration, the lobules in this portion appeared natural. In the opinion of Dr. Sharkey, who made the autopsy, this was not an infarct. Dr. Bristowe said he had not traced the vessels in similar livers and could not give a positive opinion, but he had often noticed such a change in the livers of cases in which emboli had been likely to occur.

The brain weighed two pounds and nine ounces. There was some excess of arachnoid fluid, but the convolutions appeared natural. In the left middle cerebral artery, in the fissure of Sylvius, not far from the beginning of the vessel, was found a block consisting of a central, white, firm mass with an irregular surface, surrounded on the proximal and distal sides by a dark red, recent clot. The central portion had evidently the same structure as the vegetations which had been found on the mitral valve. The left corpus striatum was much softened, the lenticular nucleus, especially at the lower and anterior extremity, being considerably less soft than the rest. The optic thalamus was little, if at all softened.

When the paralytic symptoms appeared, Dr. Bristowe's diagnosis was confirmed; it seemed pretty clear that another embolus, a bit of vegetation from the mitral valve, perhaps, had been carried away by the blood-stream and lodged in one of the arteries of the brain, probably the left middle cerebral. After the diagnosis which had been made, the lesions found at the autopsy were very satisfactory, and one of the interesting, and not the least interesting features of the case, is that so correct a diagnosis could be, and was, made during life.

Dr. Bristowe has been kind enough to add the following:

"It is very often difficult or impossible to convey by even very careful notes of a case, the impressions that have been formed by those who have been constantly watching it. In reviewing the above case from time to time down to its termination in death, certain facts and considerations rose, so to speak, to the surface, and gave it a marked individuality, which impressed it deeply on the memory. The patient was a delicate, well-conducted, uncomplaining, interesting-looking little girl; and it was a source of grief to us all that when the rheumatism had subsided, she did not recover her health, as such patients generally do, and as we had a right to expect she would have done. For although she had very obvious heart disease, this had not reacted on the system in such a way as to suggest that she was suffering yet, or was likely to suffer for some time to come, from the usual mechanical consequences of mitral disease; she had no signs of pulmonary congestion, no irregularity of pulse or congestion of surface. But she continued weak, unable to rise from her bed, and with a temperature resembling in great measure that of ordi-

[illegible] to the fever; the only difference probably being that it was more irregular in its type than he is accustomed to. The temperature recorded [illegible] of these of chronic pyæmia, and the belief that she was suffering from so-called "obstructive exhaustion," naturally presented itself to the mind. The view of her state was confirmed as the case went on; first, by the persistence of the fever and weakness; second, by the development of albuminuria, which considering that the mitral disease had not caused other constitutional symptoms, seemed best explained as being the consequence of renal embolism; and third by the enlargement and subsequent tenderness of the spleen, conditions which still more directly pointed to the occurrence of embolism. Her final attack of right hemiplegia with aphasia, obviously the result of a plug in the left middle cerebral artery, only too amply confirmed the diagnosis already arrived at.

"I do not at present recollect to what I attributed the murmur heard during life at the base of the heart. The account of it seems to imply that it was pericardial. But no trace of pericarditis was found [illegible]. I am inclined to think it must have been simply the mitral murmur heard specially loud, as it sometimes is, in the usual situation of an aortic valve murmur.

J. S. B."

Progress of Medical Science.

Simultaneous Ligature of the Femoral Artery and Vein.—Dr. Bouilly, of Paris, reports a case of wound of the femoral artery and vein, in which he was compelled to ligate both vessels simultaneously. The patient, a butcher, 24 years of age, had been stabbed with a knife in the inner side of the thigh, and had lost an immense quantity of blood. A tourniquet had been applied, but the slightest movement of the patient brought on a flow of blood from the wound. After the application of Esmarch's bandage, the wound was enlarged, and both the femoral artery and the femoral vein were found completely divided and free of clots, the artery gaping widely. The lower ends of both vessels had retracted within Hunter's canal, and were only found after careful dissection. Two ligatures were applied on each vessel. The tissues of the limb were greatly infiltrated with blood, which had penetrated along the sheath of the vessels into the popliteal space. As much of this blood as possible was squeezed out by gentle manipulations, and the wound was dressed antiseptically. The patient rallied well after the operation, but the case was reported too soon to give the ultimate result.—*Gazette Médicale de Paris*, Sept. 27, 1879.

Bigelow's Operation on a Patient Eighty-eight Years of Age.—Mr. Teevan reports a case of lithotripsy on a patient eighty-eight years of age. The urine showed no evidence of renal disease, and there was nothing in the heart or lungs to contraindicate an operation. Accordingly, on September 13th, the patient was put under the influence of ether, and in the space of twenty minutes a lithic-acid stone, measuring one inch and a quarter by one inch, was pulverized and evacuated. The calculus was excessively hard, and the noise produced by breaking up the smallest fragment was audible to all present. Three lithotrites were used, being introduced eight times in all. The evacuating tube, No. 26, which slipped in with ease, was used three times. There was a little blood lost during the operation, and for four days afterward the urine was coagulous. Much smarting was experienced for forty-eight hours whenever the water passed, but it was entirely confined to the pendulous portion of the urethra, and no excoriation was there. The slightest pain or tenderness in the hypogastric region. The highest temperature recorded was on the morning of the 15th, when it reached 101° F., the pulse being 98. The patient's progress after the operation was one of gradual improvement. The urine began to clear on the fifth day, the nights were good and the appetite keen, and on September 24th he left his bed, to which he had been confined for three months. Five days later he went for a drive. On October the 4th he was absolutely free from all pain, and was very cheerful and happy. He could hold his urine for four hours, and get a good night's rest. The urine was clear, and there was no phosphatic deposit.—*The Boston Med. and Surg. Journ.*

Acute Osteomyelitis, with Special Reference to its Causes.—The following are the most important points of a very instructive paper, by Kocher, on acute inflammation of bones. Acute osteomyelitis is produced, like other inflammations, by infection, but still it is not a *specific* infectious disease. His observations were made on 52 cases, of which, however, only 30 were positively demonstrated to be cases of osteomyelitis acuta. Of these 30 cases, 26 were males, and 4 females, all were between 8 and 25 years of age. In a few of the cases, the patients had caught cold or had received an injury; in seven cases the osteomyelitis was *secondary*, having developed in one in the course of a typhus, and in the others during the existence of inflammatory processes in different parts of the body. From these last cases Kocher deduced the conclusion that osteomyelitis is excited by the action of agents which may exist for some time in the body without giving rise to the general symptoms of infection of the bones. The bones which grow the most rapidly are the most frequently affected; hence, certain spots, such as the lower end of the femur and the upper end of the tibia, present a special *anatomical predisposition*.

In the experiments on animals several methods were employed: 1. Agents which exerted a physical or a chemical action (liquor ammonii, tinct. cantharides, ol. crotonis) were tried with antiseptic precautions. 2. Decomposing fluids and pathological secretions were injected. 3. The first method was combined with the internal administration of putrid matters. The first method, as a rule, failed, while the third succeeded. True metastases in other organs were not observed. Hence it follows, that under some circumstances irritant matters may pass from the intestinal canal into the bony marrow, and give rise to osteomyelitis.

In acute osteomyelitis, disturbances of function of the adjacent joints often precede the other symptoms; purulent effusions into the joints may also occur early. If the abscess be opened, the epiphysis will often be found separated. The pus frequently contains free fat. It is a remarkable fact that the lymph-glands are only slightly implicated. The fever is usually high from the beginning, without morning remissions, and sometimes remains high for some days after the abscess has been opened. Recovery, when it occurs, is greatly protracted by the necrosis, which almost always occurs. Death occurs either from pyæmia multiplex acuta, with metastases in the lungs, kidneys and heart, or from the development

of *secondary* inflammations in some internal organs (pyelo-nephritis, pleurisy, etc.), after the original bone disease has begun to improve. There is also danger of septicæmia after the abscesses have opened.

Kocher divides the affection into three stages from a pathologico-anatomical standpoint:

1. The stage of purulent infiltration of the medulla, with the formation of isolated foci of disease; from these the pus extends to the periosteum and synovial membrane.

2. The stage of formation of abscesses and sequestra in the cortical and spongy tissues, and in the epiphyses.

3. The stage of reparation. The osteomyelitis becomes chronic in the form of chronic osteitis, or of abscess of bone; the former terminates in osteosclerosis or in osteoporosis.

In the way of treatment, Kocher recommends the salicylate of soda in doses of ʒ iss. to ʒ vj. pro die, or if that will not be borne, alcohol in large quantities. Locally, he advises the evacuation of the pus by puncture (not by incision, so as to avoid the danger of a new point of infection), and the injection of a five per cent. solution of carbolic acid, one or more hypodermic syringefuls daily. The fluid should be injected not alone into the abscess, but also by means of hollow drills into the medulla. If the abscess have already broken, free incisions should be made down to the periosteum, and strict antiseptic dressing employed. If the joint be involved it can sometimes be saved by washing it out with a five per cent. solution of carbolic acid, but amputation will often be necessary.—*Centralblatt für Chirurgie*, No. 39, 1879.

Paroxysmal Hæmaturia.—A case of paroxysmal hæmaturia is reported by Mr. John E. Neale, the notes of which illustrate many interesting features connected with this rare condition of the urine. The onset of the disease seemed to be clearly traceable to an injury of the spine, whereas in most instances it has been ascribed to a malarial origin, or to exposure to cold and wet. Counter-irritation and quinine had apparently a great control over the paroxysms, they entirely disappearing for the space of three months after treatment was begun, although for the four months which elapsed between the receipt of the injury and his admission into the hospital, there had never been an interval of forty-eight hours between the attacks. Like most of these cases the paroxysm never occurred during the night, lasted only a few hours, while other symptoms which have been observed—viz., retching, vomiting, pains in various parts of the body, and retraction of the testicle—were always absent. The color of the urine and the absence of the usual "smoky" appearance, would immediately draw attention to the difference between this condition of the urine and ordinary hæmaturia, while its microscopical and spectroscopical characters give to it diagnostic signs, viz., the complete absence of red blood-corpuscles, a deposit consisting principally of amorphous granular matter (urates), numerous crystals of oxalate of lime, a few hæmoglobin crystals, together with pigmented masses exactly resembling those found in the spleen, liver, and thymus gland. The coloring of the urine was not due to any solution of hæmoglobin, nor to *hæmatin*, for this latter substance not only has a definite spectrum of its own, but only exists in alkaline solutions of hæmoglobin, whereas the urine in this case was always acid. Neither was it due to the presence of *hæmin*, this body always occurring in a definite, easily recognizable crystalline form. The pigmented masses observed under the microscope resembled very closely similar ones seen in the spleen, liver, old collections of blood, etc., and known as *hæmatoidin*, but where this sudden destruction of the red corpuscles and rapid transformation of the coloring matter take place is not yet capable of proof.—*The Lancet*, Nov. 15, 1879.

Citrate of Caffein.—In the January number of *The Practitioner*, Dr. Lewis Shapter recorded some observations on the use of citrate of caffein as a diuretic in cardiac dropsy. He now directs attention to its therapeutic position as a sedative and anodyne in those conditions of mental anxiety and exhaustion, and neuralgia associated with well-defined arterial relaxation and passive venous engorgement. The drug probably acts through the sympathetic system upon the heart and vessels, and it may be confidently looked to (1), to induce co-ordinate action of the heart; (2), to increase vascular pressure, and promote free and almost instantaneous diuresis; and (3), to stimulate a heart gradually being relieved of its source of embarrassment to more vigorous and forcible contraction. In addition to the diuretic and cardiac action of caffein, there is a secondary effect which is scarcely less valuable. The arterial relaxation and venous engorgement of the cerebral vascular system induce a state of malnutrition or impoverishment of the cerebral cells, resulting in a morbid state of activity. By restoring the balance of the circulation, the effete products of the cells are carried off, fresh supplies of blood brought forward, and, as a consequence, the first quiet night with refreshing sleep is passed under the influence of caffein. In migraine it has been used with a certain amount of success, which would be explained by the theory of M. Hervey, that migraine is an arterial neurosis taking origin in the great sympathetic nerves, and having its seat in the nervous filaments accompanying the arteries, the result being dilatation (or perhaps relaxation) of the vessels. It should be administered in sufficient doses, three grains of the nitrate being the minimum dose. In cases associated with pain or asthenic mental excitement the dose will probably have to be increased, and be frequently repeated; but in cases of heart disease, where it will serve as an adjuvant to digitalis, three to five grains given every night will usually be found sufficient to establish free diuresis, and induce that proper state of nutrition from which sleep, as not the least of the important ends to be attained, may be expected.—*Brain*, October, 1879.

Programme of the British Medical Association for 1880.—The next annual meeting of the British Medical Association will be held at Cambridge, under the presidency of Professor Humphrey. The address in medicine will be delivered by Dr. Bradbury, that in surgery by Mr. Timothy Holmes, and that in physiology by Dr. Michael Foster. The sections will be presided over by Dr. Paget, of Cambridge, in medicine; Mr. Savory in surgery; Professor Rutherford, of Edinburgh, in physiology; Dr. Crichton Browne in psychology; Mr. Bowman in ophthalmology; Sir James Paget in pathology. Each president will deliver an address in opening his section. The association is growing larger each year. Branches have recently been established in Jamaica and in Australia. It is probable that a branch will be organized soon in Canada. The Indian branch is to be reorganized and revived.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 10, 1880.

MEDICAL FEES.

THE medical fee question is one which has such an interest attached to it that there are few, if any, who have not given it, at some time in their professional career, their earnest attention. It is not, then, a matter of surprise that correspondence has been invited by our remarks on the subject in our former issue. We are inclined to believe the comments made in letters, to which we refer, so nearly express the general sentiment of the profession concerning collections, that we are safe in taking them as texts for more extended remarks.

It would appear scarcely fair to charge the doctor himself for much of the trouble which he experiences in collecting his fees; but such a truth becomes evident to every one who pauses to look at the situation.

In the first place, as one of our correspondents suggests, we are not careful enough in our accounts, we do not set a definite value on our services—in fact, have no absolute standard to guide us in a given grade of cases. Our prices have a wide range of fluctuation. On one extreme we strain a point to believe that many of our patients are too poor to pay anything, and on the other extreme we are inclined to stretch our consciences in charging the highest possible price to the rich. The consequence is that both rich and poor look upon the doctor's bill as a variable quantity, subject to discussion and dicker, and, as a rule, pay the amount under protest. The rich man is usually as apt at this business as his poorer neighbor. He is not content to pay more than other people, simply because he has a larger income, and is apt to look upon the doctor as taking advantage of the circumstance. Hence, he has an excuse for asking a reduction. The willingness with which the physician listens to these appeals, and makes reductions accordingly, only proves the more conclusively that the services rendered are not worth the original price charged therefor. In fact, the wider appear the margin for profit the less exact is the real value of the services they represent. Hence it is that the so-called lumping of accounts has become a fashion.

In the second place, as has also been suggested by our correspondent the practitioner should keep accurate accounts of his visits. They should represent so much actual hard work performed. He responds to those calls sometimes at great disadvantage to himself, and often at a sacrifice of rest and sleep. He, as a business man, should expect to be paid for each and every one of them.

The patient has no more right to demand the reduction of the bill after these services have been performed than he has of asking that they be performed for nothing at the start. But, unfortunately for the poor doctor, he is no business man, and is too apt to forget what he really has done in his desire to accommodate his patron with what the latter may call "a reasonable bill."

Again, viewed in a purely business light, each physician should not only make his own standard of prices, keep exact accounts, but insist upon full payment. It is always better to make the patient who is unable to pay the full amount a present of the balance due than to deduct the same from the bill. A receipt for the full account of the bill, even if it represents only one half the sum of the same, proves to the patient that the services are worth none the less because he cannot pay for them in full. If such a rule were adopted, medical services would have a definite value, which could not be questioned by any and every one who might think that he is doing the doctor a service by paying his bill at all.

Of course it would be absurd to charge the poor man a bill he never can pay. His circumstances must be taken into account, and the amount of the bill regulated accordingly. When once the sum is fixed, however, it should remain so, and partial payments should either be credited on account or the bill receipted for the same in full. We should fix a low rate for the poor, not because our services to them are less valuable than to the rich, but because they are unable to pay more. The same principle should hold good regarding our bills to the wealthy. The latter should pay the full value of our services, but no more.

It is right to assume that the rich only can afford to pay the physician his just dues—to give a fair equivalent in money for services rendered. But this idea cannot in justice be carried to the extent of making our charges extravagant, or of laying us open to the suspicion of extortion. No one better than the attending physician knows how much his well-to-do patient should pay, and he should fix the sum as a definite one, and insist, as a matter of principle, that no deduction on account of the real value of services should

be allowed. If such rules were followed out in the proper spirit, the patient would not be tempted so often to ask for reductions, neither would the physician be persuaded to grant them, thus placing a mere nominal value upon his professional opinions.

In regard to itemizing bills, as recommended, this is not always possible, especially when the services are varied in character and consume variable periods of time. It is advisable, however, to fix a value upon each particular visit at the time of making the same. When such a practice is carried out there will be no trouble of giving the details in the bills, if such be desired. This is certainly the accurate and business-like way not only of keeping accounts, but of rendering them, and avoids that guessing at amounts at the end of the year, which is alike disadvantageous to the patient and the physician.

The recommendation of another of our correspondents to send monthly accounts to our patients is worthy of consideration. There is no doubting the fact that the longer bills are allowed to run the larger they are apt to become, and the more unwillingly are they paid. It is a bad fashion which sanctions the presentation of accounts not oftener than every six months. The well-to-do practitioner does so, and his impecunious brother is conventionally compelled to to do likewise. Somehow or other it is considered undignified for the physician to be in any seeming hurry to present his account. It must consequently be more genteel for him to owe his butcher and baker than ask money of those who owe him. There is a false modesty in this that is ridiculous to the business man. The only one who suffers by it in the long run is the doctor himself. No man who has been in practice need be told that money should never be refused when it is offered; and yet he is, by the half-yearly and yearly system of sending out bills, practically encouraging the patient in becoming a delinquent debtor. The best time to present the bill is when the services are terminated, and, if the patient is unable to pay at that time, it is better that he should think the delay was due to his carelessness rather than to the want of ordinary business tact in his medical attendant.

FURTHER EXPERT TESTIMONY AT THE HAYDEN TRIAL.

Further expert testimony has recently been put in by the defence at the Hayden trial, and has furnished statements of considerable interest. In our previous comments on this trial, we mentioned that the three principal points upon which the testimony bore were: the symptoms and signs which may be produced by the presence of a small ovarian cyst; the tests for blood; and the possibility of distinguishing different samples of arsenic, by the proportion of crystals to amorphous particles seen under the microscope.

The victim, Mary Stannard, was found to have a small ovarian cyst, about three-fourths of an inch in diameter. In was claimed by the prosecution that this had given rise to symptoms of pregnancy, and that she had been killed by the defendant in order to avoid the public exposure which her supposed pregnancy would cause.

It will at once appear that the idea of a cyst, so small in size, producing symptoms of pregnancy, can only be characterized as absurd. It cannot, perhaps, be absolutely denied that such a tumor may produce some symptoms, since few things can be absolutely denied in medicine. But that such remote possibility of some ovarian irritation should be taken as the basis of a theory of prosecution, shows alike a poverty of theories and of medical knowledge. Such tumors are not very unfrequently found at the post-mortem table, no evidence of their presence having previously been given. They are even found before the age of puberty, and may sometimes remain stationary and undeveloped. The ingenuity of an imaginative legal mind may make it appear probable to the jury, that because the young woman had a small cyst, therefore she had the symptoms of pregnancy; but we do not see how they secured medical experts to help them along. She might have been hysterical, she might have been an excellent case for a gynecologist and a medicated pessary; but she could only by the rarest coincidence have furnished the signs of pregnancy. To this effect the experts for the defence testified.

The counter-testimony, in regard to the detection of various samples of arsenic, was not very extended. It was asserted that, owing to peculiarities in the grinding of arsenic, the same manufactory might send out lots in which the proportion of crystals would vary. On the whole it seems likely that, as we have stated before, the determination of the source of arsenic by its microscopical appearance can rarely be a certain one. The value of the discovery, therefore, of a varying proportion of crystals in different lots, must, from a medico-legal point, be quite limited.

The question of the tests for blood was testified upon at considerable length. The experts secured for the defence were unanimously positive that human blood could only be distinguished from that of certain other mammals under rare and very favorable conditions, if at all. This was in direct contradiction to the evidence for the prosecution. Dr. Woodward testified that the size of human blood-corpuscles in different persons was as variable as that of the individual; and that the size also varied greatly even in the same animal. The range was said to be greater in disease and in the young. This variability applied not only to man, but the lower mammals. It would take, said the witness, forty-two years to find the true average size of the corpuscles of any animal. Alluding to the history of such measurements, the

great variance of opinion during different periods was shown. Thus Gulliver, in 1878, made the average diameter 1-3250 of an inch; Hewson in 1864 found it to be 1-3000 of an inch; Wharton Jones, 1-3000 to 1-4000; Kölliker, 1-3200 to 1-4000 of an inch. The most recent authoritative measurements make the average diameter 1-3620 of an inch. Dr. Woodward took, in general, a very positive view of the case. His statements are, however, to a great extent misleading. When it was first undertaken to measure blood-corpuscles, there was no authorized definite standard for the micrometer; nor was it until recently that the lack of a definite standard has been overcome. The variation in measurements, therefore, by different observers, may indicate variation in micrometers rather than in the corpuscles. An examination of the different sets of measurements will show a substantial agreement as to the relative size of human corpuscles, compared with that of other animals. The statements concerning the great variability in the size of the blood-corpuscles are not in accordance with those of the majority of microscopists. Physiologists state that the red blood-corpuscle varies less in size than other anatomical elements. Kölliker asserts that ninety-five per cent. are of the same size. It is generally agreed that man's red blood-corpuscles are larger than those of any of the ordinary domestic animals from which distinction has generally to be made.

In the present case the defendant testified that he had killed chickens with the knife in whose notch corpuscles were found. Since it would be comparatively easy to distinguish the oval corpuscles of the fowl, we were inclined to lay some weight on the testimony of the experts for the prosecution. The impression given by Dr. Woodward as to the exceeding vagueness and inaccuracy of microscopic measurements was unjustifiably strong.

The possibility of distinguishing, under proper conditions, the human blood from that of other animals, cannot be denied. The possibility of being able to do it, however, in any particular case with sufficient certainty to swear away a life, is another thing entirely, and one in which we do not believe. In the present case, although the scalpel discovered an ovarian tumor, and the microscope arsenical crystals, and possibly human blood, there was nothing established by the expert testimony strong enough to warrant a verdict of guilty.

DEATH FROM CHLOROFORM IN A DENTIST'S CHAIR.

It is our painful duty to record another death from chloroform in a dentist's chair. The patient was a young man, 21 years of age, and the place where the accident occurred was St. Johnsbury, Vt. No details are given—simply that death was the result of the administration of chloroform. To most physicians such a statement is enough to bring to mind the usual relations of cause and effect in these cases, and to engender a growing conviction that this dangerous anæsthetic should be banished from the dental operating room. In view of the number of deaths from chloroform during dental operations, and the usual distressing circumstances which attend them, it is to be hoped that any dentist should, even under the most extraordinary circumstances, run any risks with his patient. We are not prepared to say that the dentist did not use all the ordinary precautions in relation to anæsthesia. Probably he did. But he used trichloride chloroform as the agent, and for this he is certainly in the highest degree culpable.

THE CARE OF THE POOR.

In a recent report of the Society for Improving the Condition of the Poor, it is stated that nearly fifty per cent. of the applications for relief are unworthy of the name. The exact figures are 42 per cent. The system of relief comprises a personal examination of the claims of each applicant, a visit to his abode, and any other means which may be considered necessary to guard against misrepresentations. Consequently, the statistics may be considered trustworthy. Possibly such figures may serve to point a moral regarding dispensary relief, and show perhaps how many are treated for nothing who do not deserve such service. At least, the adoption of similar means of inspection would tend to lessen the number of medical paupers.

SURGEONS IN PUBLIC JOURNALS.

The success of Dr. Keith in performing ovariotomy has recently been very extraordinary. He reports seventy successive operations without a death. This and his previous record have secured for him a remarkable prominence. An article appeared in the *Scotsman*, a leading lay journal, not long ago, giving some account of the operation of ovariotomy, reciting the surgical performances of Dr. Keith, and sounding the praises of that eminent gentleman very highly. There can be no doubt at all that nothing was said in regard to Dr. Keith's character, accomplishments, or history, which is not strictly true, and the *Scotsman* very properly took much credit to its country for having produced a man capable of rendering such services to humanity.

It does seem, on first thought, only just that the great advances which surgery and medicine are making should at times be announced to the general public, even though it cannot be done without referring to particular persons. Nevertheless, we are of opinion that such a publication as appeared in the *Scotsman* is neither in good taste nor for the true benefit of the profession. It is always difficult to show the laity what really constitutes scientific prog-

ress, or to teach them what is true and what factitious worth. A medical man does not get credit in proportion to his merits. An incision of the frænum linguæ, or the happy administration of a carminative, may send one at once to giddy eminence or lay the foundation of a life-long reputation. On account of such facts, together with the liability to jealousies and hard-feeling, the profession has always deprecated, and its ethics have forbidden, any public announcement of particular medical or surgical attainments. Further, it is difficult for any one who is acquainted with the way in which eminent operators look out for their "record," to feel unalloyed triumph over the announcement of an extraordinary number of consecutive successful cases. Was there no selection, no turning over of doubtful cases, no refusal to give a patient the very last chance? Have we a genius who never fails in diagnosis, who can foresee every contingency and meet every complication with unerring judgment? If so, then humanity should rejoice; but it is a wide experience which finds such men.

THE ANATOMICAL USES OF THE CAT.

It was philanthropic as well as practical on the part of Dr. Burt G. Wilder to suggest the more extended use of the cat for dissecting purposes. It seems to be well admitted that cats are increasing faster, proportionately, than the population which supports them. And, applying the doctrines of Malthus, the cat rises to a numerical prominence in the civilization of the future which is quite alarming. The cat in moderation is a useful addition to the household, and gives, we may say, rotundity and completeness to the domestic life. But cats in excess are annoying, and the proposal to make them the subjects of anatomical study by medical students is a welcome and judicious one.

The anatomy of the cat is very much like that of man; the resemblance being closer than that of most other domestic animals. The viscera have nearly the same arrangement; the brain has the primary divisions, and even some of the fissures which are found in man. Most of the cranial nerves may be easily discovered. The bones and many of the muscles can be identified from a knowledge of Gray or Quain alone.

There are many drawbacks to the successful study of anatomy upon the human body. The expense is considerable, the subject may be bad, progress is always slow, and there is, as a rule, very little systematic study in connection with the work. Dissection and examination of the viscera are greatly neglected, and yet they are the most important parts for the majority of students. It is very likely, therefore, that preliminary dissections of an animal so easily obtained and cared for as the cat would be of great help to the student. While studying under a preceptor or while pursuing any course of preliminary training, he could easily occupy part of his time in such anatomical investigations. He would thus acquire a practical familiarity with the use of the knives, the appearance of the organs and tissues, and the names and general arrangement of most of the structures of the human body. An interest in comparative anatomy would also be often excited, and such an interest is always valuable as stimulating to more earnest and thorough investigation.

The numerical decrease of cats and the quantitative increase of anatomical knowledge are two things which it would be desirable to bring about. We hope that undue stress has not been laid upon the former.

THE COLOR OF OUR CLOTHES.

A very learned discussion has been given by the *Lancet* on the subject of colors and the caloric properties of clothes. It was ingeniously argued that, as white is the best reflector of heat, it is therefore the worst conductor of the same. Light clothes are, therefore, the warmer, and should be more universally adopted in the winter months. This somewhat arbitrary logic was enforced by an illustration in natural history, which does not show any deep or varied acquaintance with that department of human knowledge. The polar bear was instanced as an evidence that nature coincided with the views of the editorial annotator. Now, since for hundreds of years it has been the practice to wear dark clothes in winter, and light clothes in summer, we may presume that there is a good practical reason at the bottom for so doing. At any rate, it has been shown by Tyndall, that although the color of a substance may materially affect the rate with which it will become heated by the luminous heat of the sun, yet color has no effect on the radiation of non-luminous heat. Such kind of heat is being thrown off from our bodies, and the amount, therefore, thus thrown off depends on the conductivity, not the color, of the garments. Dark clothes absorb heat from the sun and do not affect the radiation of heat from the body. The popular habits in regard to clothes are thus, as might be expected, justified by the investigations of science.

As to the polar bear, there are other reasons for explaining the whiteness of his fur. A beast that roams for prey upon an iceberg or along snowy shores would have little chance of succeeding in its predatory inclinations if it were made conspicuous with a dark coat.

It will be found that animals which inhabit the tropics have, as a rule, rather light furs. It is in the temperate region, where the snow is only temporary, yet where low temperatures often prevail for some time, that the average color is darkest.

THE DECLINE OF IRIDECTOMY.

In a paper by Dr. De Wecker, read in the Ophthalmological Section of the late meeting of the British

...Medical Association, it was stated that iridectomy had been performed in forty-eight cases for the cure of simple chronic glaucoma. The results had all of them been good. This subject of the selection of iridectomy for iridectomy has recently been discussed at length before the Surgical Society of Ireland. Mr. Swanzy read a paper in which he advocated the method of treatment, as furnishing much better results than iridectomy, in simple chronic glaucoma. The general tone of the discussion that followed suggested a waning confidence in iridectomy, and it appears that this much lauded operation is ceasing to be so much in fashion. The theories on which it was founded have always been somewhat vague and imperfectly proved; they necessarily differed in accordance with the views taken of the pathology of glaucoma. An increased delicateness has of late been given to the latter, and this fact helps to a more intelligent line of conduct in operating. The prominent symptom in glaucoma is an increased hardness of the eyeball, due to its being overfull. It has been shown that the chief point of escape for effete intraocular fluids is at the angle of the anterior chamber, passing outward through the ligamentum pectinatum into the canal of Schlemm. It has been further shown that in glaucoma this way of exit is obstructed by the adhesion of the periphery of the iris to the periphery of the cornea. Now De Wecker has long contended that the establishment of a cicatrix at the corneo-sclerotic margin offers a new chance for the transudation of the intra-ocular fluids, thus relieving the tension. The microscope discloses that in these cicatrices the margins are not intimately opposed, but that there is a semi transparent substance interposed, which probably allows the passage of the intraocular fluids.

This theory is plausible enough, but must await further facts for its confirmation. In the meanwhile it will be interesting to observe whether iridectomy is to be largely laid away among other ephemeral fancies of enthusiastic specialists. It is pretty certain, at least, that it will not be performed as often in the future as in the past fifteen or twenty years.

THE ENLARGEMENT OF THE MEDICAL RECORD.

With the present number the MEDICAL RECORD will be again enlarged by four pages of reading matter in each number. This increase seems to be warranted, not only on account of the expansion of the subscription list, but by the extra number of advertising sheets which have been added to the journal. We shall thus be enabled to give to our readers over two hundred pages more in the year than they have been accustomed to receive, and without extra expense to them. With the increased facilities which these additional pages will afford, we hope to make the RECORD more and more interesting and useful to the general practitioner.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY

Stated Meeting, Dec. 10, 1879.

DR. E. L. KEYES, PRESIDENT, IN THE CHAIR.

CANCER OF AXILLARY GLANDS.

DR. POST exhibited specimens of cancerous degeneration of the axillary glands, removed by operation from a patient upon whom, fifteen months before, amputation of the breast had been performed for the same disease affecting that organ. The growth was in close proximity to the axillary vessels, and a very careful dissection was necessary.

A FINGER FOR A NOSE.

He also exhibited a nail with matrix attached, which he had removed from the ring finger of the patient upon whom he had operated for lupus of the face. The parts had nearly healed, and it was his intention to construct a nose with the ring finger, which he intended to amputate for the purpose. As a preliminary procedure, in such an operation, the nail had been removed.

TUMOR OF UPPER JAW.

DR. POST also presented a tumor of the upper jaw, removed by operation in the New York Hospital, from a patient aged sixty years. The growth originated in the alveolar process, and extended to the antrum, occupying its lower part but not expanding its walls. The lower portion of the maxilla was removed with the tumor, leaving the lower margin of the orbit intact. Blood was prevented from entering the larynx by keeping the head in a dependent position over the edge of the table.

DR. JANEWAY exhibited an interesting tumor of the pons, of large size, which he had diagnosticated before death.

THROMBOSIS OF HEART AS A CAUSE OF DEATH.

He also exhibited the heart and lungs of a patient who had died with cardiac thrombosis. The right lung was the seat of lobular pneumonia with pleurisy, serous and adhesive, and whispering pectoriloquy, with bronchophony and vocal fremitus, were heard below the level of the fluid. Dr. Janeway believed that the cause of death was primarily thrombosis of the heart. At the autopsy, the clot was soft and well formed.

DR. LOOMIS remarked that the author who gave the clearest explanation for the existence of vocal fremitus, bronchial breathing, and bronchophony in connection with pleural effusion, was Dr. Stokes. That gentleman said that in such cases there would always be found compressed lung, but not compressed bronchial tubes. So long as the bronchial tubes remained pervious, and extended below the level of the fluid, the physical signs referred to would be heard. The existence of pectoriloquy depended a great deal on the character of the voice, some patients giving it through healthy lung. He thought that all vocal signs were very unreliable.

Dr. Loomis did not believe that the thrombosis was the primary cause of death. The clot was recent, soft, and offered no marked obstruction to the blood-current.

Dr. Janeway contended that only the outer portion of the clot was soft, and that, by its rapid formation, it clogged the valves and arrested the heart's action.

THE SKIN IN HYPODERMIC INJECTIONS.

Dr. Amidon exhibited several sections of skin showing the effects of hypodermic injections. He had selected, for purposes of observation, patients in a moribund condition, and had administered hypodermic injection of solutions of indigo. In such as possessed very little adipose tissue, the coloring-matter collected in a plane immediately below the level of the true skin, and in fat subjects the injection diffused itself widely throughout the cellular tissue of the interlobular spaces. He referred, in this connection, to some experiments which he had made with a view of determining whether hypodermic medicines were absorbed through the lymphatic or through the circulatory system. He had found that the physiological effects of muriate of pilocarpine were manifested just as quickly, whether the injection was made at the ankle or supra-clavicular space. This being the case, he concluded that the injection was absorbed by the blood. If there had been a difference as to time in favor of the injection into the supra-clavicular space, as compared with that of the ankle, the lymphatic system would seem to have been the factor in the absorbing process.

PYÆMIA WITH THE CLINICAL HISTORY OF SEPTICÆMIA.

Dr. Loomis presented the heart, uterus, and kidneys, taken from a young woman aged twenty-one years, who was admitted into Bellevue on the 2d of December. She stated that she had always been well up to the time of her present illness, with the exception of acute articular rheumatism two years before, which, however, was not accompanied or followed by any cardiac symptoms. She had, at that time, been married about four months. She menstruated once after her marriage. Two weeks before her admission she began to have a discharge of blood from her vagina, which continued about twenty-four hours, when she began to have pains in her back and other symptoms of miscarriage. The second day after the pains commenced, her physician removed an ovum and portion of the placenta by means of the uterine forceps. The mass removed was offensive in odor. A moderate flow continued for two or three days, and was normal in character. The patient was able to be up on the third day. On the evening of that day she had a long and severe chill, followed by a rapid rise in temperature. On the fourth day these symptoms were repeated, and the fever continued. She became somewhat delirious. Ten days after the discharge of the ovum she was admitted to Bellevue. At the time of admission her temperature was 105° F., her face was flushed, her pulse was 120 and feeble. She was restless, delirious, and lethargic, but could be aroused, and then would answer questions intelligently. She was given antiperiodic doses of quinine, and the following morning her temperature was reduced to 101°. She was then more lethargic than the night before, and vomited for the first time. Vomiting then became constant. She complained of no pain and presented very much the appearance of a patient with acute mania, yet she had no desire to get out of bed, nor did she require restraint. She was constantly mumbling to herself, but would not answer questions, although she seemed to understand their import. Before noon her temperature rose again, reaching 105° F. Although she was placed upon a water-bed, treated with cold, with large doses of quinine and salicine, no impression was made upon her temperature, and she died the third day after admission. Toward the last her pulse became more frequent than before. She had no symptoms of pulmonary disease, no cough nor expectoration. There was a blowing murmur heard with the first sound, at the base of the heart. It was a question whether this murmur was due to acute changes, or was due to endocarditis, which might have been developed during her attack of rheumatism. She died in the condition of coma, into which she passed twelve hours before her death.

At the autopsy the uterus, as was expected, was found enlarged. In its upper and anterior portion it contained a small fragment of placenta. Just within the internal os was a slough which penetrated deeply into the uterine structure. There were no evidences of inflammation in the region of the uterus, no pus in the veins, nor thrombi. Infarctions were found in the kidneys. In the spleen there were a number of infarctions, some of them having undergone softening. There were evidences of old endocarditis in the left heart near the aortic valves. There were extravasations in the substance of the heart, and at one point were evidences of myocarditis. Some of the vessels of the spleen were found completely obstructed by bacteria. Bacteria were also found in a number of other organs. The point of interest to Dr. Loomis was the occurrence of pyæmia, with the clinical history of septicæmia. The dates were fixed for determining the length of time which elapsed between the removal of the fatty placenta and the onset of constitutional symptoms.

A discussion then ensued bearing upon the question whether the bacteria were the cause or effect of the pathological changes, but as no conclusion was arrived at, the Society went into Executive Session.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, Dec. 9, 1879.

Dr. H. B. Sands, President, in the Chair.

The Society was called to order at 8.15 P.M., and the minutes of the last stated meeting were read by the secretary, Dr. Chas. McBurney.

EXTIRPATION OF THE LARYNX.

Dr. Lange read a paper on extirpation of the larynx, in which he gave a résumé of the literature of the subject, and reported a successful case operated upon in October, 1879. The patient was doing very well, and was able, by the aid of an apparatus, to swallow thick soup.

CANCER OF THE LARYNX—SUCCESSFUL REMOVAL—MALIGNANT DISEASE OF THE SUPRA-RENAL CAPSULES, KIDNEY, AND URETER.

The President presented a larynx from which a cancerous growth had been successfully removed by thyrotomy. The specimen was obtained from the body of a woman who, when operated upon, was thirty years of age. She was a patient in St. Luke's Hospital, and the operation was performed in 1863, for the removal of a cancer springing from the left ventricle of the larynx. She was sent to the hospital on account of aphonia, and, not being familiar with laryngoscopic manipulation, he asked Dr. Simrock to examine the case, who discovered a laryngeal growth that at first seemed to be attached by a narrow pedi-

duct to the floor of the left ventricle. After repeated examinations, however, both Dr. Sturgis and Dr. Sands became convinced that it was not a pedunculated but a sessile tumor of considerable size, and projecting toward the axis of the larynx. Many years a portion of the growth was removed, and, when examined microscopically, it was found to be a sarcoma. Dr. Sturgis, therefore, abandoned the idea of attempting to remove it by means of a snare, and the woman came under Dr. Sands's care at St. Luke's Hospital, where, assisted by Dr. Markoe and the other surgeons of the hospital, he removed the tumor by splitting the larynx in the median line over the edges of the wound, in order to cut off by the scissors that portion which projected beyond the plane of the vocal cords. The remaining portion was destroyed by means of the actual cautery.

The patient made a rapid recovery, and, to a considerable degree, recovered her voice. She remained in excellent health from February, 1878, until October, 1878, when she came to Dr. Sands, complaining of weakness, had a cachectic appearance, and although he was not able to make a positive diagnosis, he inferred that she had malignant disease of some organ in the abdominal cavity. She then entered the New York Hospital; no positive diagnosis was made, although, from the peculiar appearance of the skin, disease of the supra-renal capsule was suspected, and at the end of twenty-two months after the operation she died.

At autopsy, both supra-renal capsules were found diseased, one being enlarged so as to measure, in its long diameter, three and a half inches, and weigh two ounces. There were also deposits of new growth in the left kidney, and the entire left ureter was converted into an almost solid cord, its calibre being only sufficient to admit a small probe. Microscopical examination of the new growth, found in various places, revealed cell-formation differing from that found in the larynx. In the larynx the tumor contained alveoli filled with epithelial cells, while the specimens removed from the abdominal cavity contained spindle-shaped cells such as were, at that time, supposed to be characteristic of recurrent fibroid.

After the operation was performed, the patient made no complaint concerning the larynx, nor was any recurrent growth found in the larynx at the autopsy.

NECROSIS OF THE RADIUS.

Dr. James L. Little presented a sequestrum representing almost the entire length of the radius, and removed from a child four years of age. About four months ago the child twisted its arm, and the injury was followed by abscess and permanent sinuses. There was a well-formed involucrum, and two openings, one near the elbow, and the other near the wrist-joint. There was no loss of bony substance, except the portion removed. The incision extended almost the entire length of the forearm. The epiphysis remained.

Dr. Weir asked why so long an incision was made.

Dr. Little replied that he began the incision at the upper extremity of the radius, where the abscess pointed first, and, continuing it down to about the middle of the forearm, found that the burrowing had extended nearly down to the wrist. No special hemorrhage occurred.

CYSTIC DEGENERATION OF THE APPENDIX VERMIFORMIS.

Dr. Robert F. Weir reported a case of cystic degeneration of the appendix vermiformis, occurring in a patient from Savannah (ga., at 55 years, who came to him in October, 1879, with a tumor situated in the right iliac fossa. There was a great swelling above the crest of the ilium, and an opening near the posterior part of the ilium, from which was discharged daily three or four ounces of pale clear mucus, occasionally tinged with pus. The case had the following history: In the summer of 1878 the patient traveled from Memphis, Tenn., to Richmond, Va., in a continuous journey. He experienced no special inconvenience while making the trip, except some irregularity of the bowels and weariness, but soon after his arrival he had a chill that was followed by a fever, which lasted two or three weeks and then subsided.

In December he was again seized by a chill, and then he suffered a great deal of pain in the right side of the abdomen, low down, and the pain ran down the thighs, sometimes affecting a single muscle, and was associated with fever of a remittent type, lasting about ten days. A third attack occurred in February, 1879, and was attended by pain. He lost flesh and strength during the spring, was somewhat lame, but his disease was not diagnosticated. No attention was given to the iliac fossa until September last, when he noticed a tumor there about the size of an egg, and apparently attached to the inner surface of the ilium. Just about ten days afterward it was outside of the bone, was opened, and three or four ounces of glairy fluid were discharged.

He then came under Dr. Weir's observation, who found a tumor somewhat tender upon pressure, situated in the right iliac fossa, just in the position in which tumors in that region are developed as the result of inflammatory action. Pressure caused it to discharge a thick, glairy fluid, and when a Nélaton catheter was introduced into the opening it could be carried in about eight inches.

Examination of the fluid, microscopical and otherwise, gave negative results.

Dr. Sands then saw the case with him, and recognized that the discharge came from a mucous surface, but did not arrive at any positive conclusion with reference to the seat of lesion.

On consulting books, he finally found in Virchow an account of *colloid degeneration* of the appendix vermiformis; and also found an account of the same in "Reynolds's System of Medicine." He also learned that Drs. Sabine and Delafield jointly saw a case in Bellevue Hospital, where the opening was about two inches above Poupart's ligament. Dr. Delafield was invited to see his case, and reached the conclusion that it was one of this variety.

The patient's general and local condition was then improving, and he was advised not to have anything done locally, so long as improvement continued; but when it came to a standstill, it was thought proper that the cavity should be injected with iodine, gradually increasing the strength of the solution used. In the meantime a highly supporting plan of general treatment was adopted.

Dr. T. T. Sabine gave the following history of the case to which Dr. Weir had referred: The patient came into Bellevue Hospital about two years ago. He had formerly been there for a similar trouble; the tumor was about the same size; the opening had healed, and he had been discharged.

When he returned to the hospital, Dr. Sabine found a swelling in the iliac fossa, two inches above Poupart's ligament and two inches to the inner side. The integument covering it was thin, slightly reddened, but the sense of fluctuation was not very prominent. He opened it, and at once was struck

with the peculiar character of the fluid discharged; it was glairy, almost transparent. When a probe was introduced it passed in a direction nearly backward, with a slight inclination upward, and he was unable to understand whence the fluid came. On consulting authorities, he found Virchow's account of colloid degeneration of the appendix vermiformis, referred to by Dr. Weir, and he also asked Dr. Delafield to see the case with him, and called his attention to Virchow's statement, when he agreed that it might probably be a case of that kind.

Dr. Sands remarked that the fluid discharged in Dr. Weir's case looked almost exactly like vitreous humor.

DISLOCATION AT THE SHOULDER-JOINT—RUPTURE OF A BLOOD-VESSEL.

The President reported a case as follows: Four weeks ago he was called by Dr. Rockwell, of Brooklyn, to see a lady eighty-six years of age, who, seven or eight weeks previously, had had her right shoulder dislocated downwards. She was seen by a gentleman in Connecticut soon after the accident, and he reduced it without special difficulty. About ten days afterwards the dislocation was reproduced, and then nothing was done towards placing the head of the bone in position until she came to Brooklyn, when Dr. Rockwell made a slight attempt to restore it to its place, but without success. Dr. Sands was asked to give an opinion regarding the propriety of making an effort at reduction, and he said that he regarded it as dangerous, and advised against it, but that if the friends and the patient desired, he would make a moderate attempt to put the bone in place. The lady expressed her desire and willingness to have something done; so she was anæsthetized with ether, and what he regarded as a very moderate effort to reduce the dislocated bone was begun by putting the left hand in the axilla, while with the right, using the arm as a lever, movements usually resorted to in breaking up adhesions were made. Evidently some of the adhesions did rupture, and after continuing the movements for three or four minutes, a sheet was placed around the patient's waist, and held from the opposite side by Dr. Rockwell's wife, while slight traction was made upward and outward, no towel being used for the purpose. The amount of traction was nothing like what he should have regarded as prudent to make, when it was stopped in order to readjust the band about the waist. While arranging to make a second attempt—five or six minutes—he thought he perceived a swelling in the axilla, and called Dr. Rockwell's attention to it, who thought it merely superficial and caused by the pressure from the bandage, and found what to him seemed to be the same condition upon the opposite side. Dr. Sands, however, removed the sheet, when it was very apparent that a blood-vessel had given way; there was a quite rapid increase of the swelling in the axillary region, and it was very soon as large as the head of a child at term. There was no pulsation in the radial, the ulnar, or the brachial artery. Feeling very certain that some large blood-vessel had ruptured, he was apprehensive regarding the ultimate result. Nothing in the way of treatment was done except to place the arm by the side and apply a bandage, but within half an hour the skin in the axilla had begun to show discoloration, and within a few hours the discoloration was very marked and extended up to the shoulder. The patient was excessively prostrated by the accident, and at one time it seemed not improbable that she might die from syncope. Hypodermic injections of brandy were given, and brandy by the mouth as soon as it could be swallowed, but she remained in a very low condition for several days, especially at night. In the course of the next day after the accident the extravasation gave signs of its presence quite well, down upon the side of the chest, and later it could be readily seen upon the side of the body as low as the side of the pelvis. The discoloration behind covered nearly the entire scapular region. There was neither fluctuation nor murmur over the region of extravasation. Nothing more serious had as yet occurred; there had been gradual improvement, and although pulsation had not returned in any of the arteries of the right arm, the limb presented no unfavorable appearance. The patient made no special complaint, except with reference to a very uncomfortable tingling, at times, along the distribution of the ulnar nerve. He thought that no other vessel except the axillary artery was ruptured, was gratified at an unexpected recovery from so dangerous an accident, and was surprised that such a rupture should occur from the use of so slight an amount of force. There was no interference with the general nutrition of the limb.

Dr. Weir referred to cases, reported by Gibson, in which rupture of the axillary artery occurred while extension was being made in the same direction—that is, upward.

Dr. Erskine Mason referred to Pancoast's case, in which the artery was at once tied beyond the point of rupture.

Dr. T. M. Markoe remarked that extravasation from a broken vessel was an interesting feature, and it was made more interesting by the fact that the patient recovered. He had had rupture of a vessel, with extravasation, occur twice in connection with fracture, and in both cases the accident was so alarming that he set them down as probably fatal, but recovery took place.

He had a case under observation in which, after receipt of the fracture at the middle of the thigh, ecchymosis increased rapidly, extended to the lower part of the limb, had associated with it fluctuation, although no pulsation could be felt. The leg was very much everted, and no pulsation could be felt in the anterior tibial artery. The limb was left in the position in which it was found at the time the accident occurred, because he was unwilling to make any traction. Cold water and pressure carefully adjusted to the thigh were resorted to, and to his surprise the swelling from day to day diminished, the pain gradually subsided, the ecchymosis disappeared, and, after about ten days, the swelling had become so reduced that the fragments could be placed in proper position, and the result had been very satisfactory.

The other case was one brought into the New York Hospital. It was a fracture of the tibia, and the anterior tibial artery was ruptured, as evidenced by a pulsating tumor communicating with the vessel. In that case also the fluid was gradually absorbed, and no evil consequences followed. He hesitated to make pressure in his cases because he feared such interference with the capillary circulation might jeopardize the safety of the limb. He therefore omitted pressure, and for a few hours kept ice-cold applications to the limbs. He thought such extravasation as occurred in Dr. Sands's case was rare.

The President remarked that it was rare, yet there were a number of reported cases in which large extravasations had appeared in these attempts at re-

duction of dislocation, and then gradually disappeared and the patients recovered.

Dr. Mason referred to a case which came into Bellevue Hospital, a fracture of the femur, with so great an extravasation of blood that some of the surgeons supposed the femoral artery had been ruptured. The swelling about the knee was very large, but it had no pulsation. The limb was snugly bandaged from the toes up, was renewed night and morning, and the patient eventually recovered, but for several days the limb appeared as though it might become gangrenous. He applied the bandage at the suggestion of Dr. James R. Wood, who had employed it successfully in two cases in which the artery had ruptured in popliteal aneurism.

The President referred to a case, occurring in Buffalo, N. Y., in which both shoulders were dislocated while the patient was in convulsions. He was forty-five years of age. The double dislocation was overlooked, and, upon one side, it remained some twelve or thirteen weeks, when Dr. Sands saw him, adjusted pulleys, and made powerful extension. He was nearly discouraged regarding its reduction, when suddenly it slipped into place and no subsequent extra trouble was experienced. Dr. Boardman, of Buffalo, had already applied to his arm sixty pounds weight without harm or success. He also referred to a case occurring in Dr. Willard Parker's practice, in which great force was applied in attempting to reduce a dislocation at the shoulder, occurring in a patient seventy-six years old, and the humerus was fractured through the surgical neck. He had not before seen a rupture of a blood-vessel.

Dr. Mason referred to a case in which the arm was broken by very gentle manipulation.

Dr. Weir referred to cases, reported by Watson and Buck, in which the humerus and femur respectively had been so fractured, but it was done by the rotary motion.

PERCENTAGE OF CARBOLIC ACID IN CARBOLIZED GAUZE AND JUTE.

Dr. Robert F. Weir, to correct a mistake which he had made in print (*Am. Journ. Med. Sciences*), gave the result of the analysis made by E. G. Love, Ph.D., of seven specimens of carbolized gauze and jute. The analyses were all made November 18, 1879.

The first specimen of carbolized jute was prepared according to the New York Hospital formula, July 12, 1879, and was found to contain 1.46 per cent. carb. acid.

The second, carbolized gauze, New York Hospital, Lister's formula, was prepared September 23, 1879, and contained 1.57 per cent. carb. acid.

The third, carbolized gauze, Roosevelt Hospital, Lister's formula, was prepared August 27, 1879, and contained 1.44 per cent. carb. acid.

The fourth, carbolized jute, Roosevelt Hospital, Munich formula, was prepared November 9, 1879, and contained 2.95 per cent. of carb. acid.

The fifth, carbolized jute, Roosevelt Hospital formula, was prepared October 31, 1879, and contained 4.56 per cent. carb. acid.

The sixth, carbolized jute, possibly Roosevelt Hospital formula, was prepared October 20, 1879, and contained 5.83 per cent. carb. acid.

The seventh, carbolized jute, New York Hospital formula, was prepared November 13, 1879, and contained 5.56 per cent. carb. acid.

Fresh carbolized jute, if properly prepared, should contain from 5 to 6 per cent. of carbolic acid.

The New York and the Roosevelt Hospital formula is as follow: Carbolic acid, 10 per cent.; resin, 40 per cent.; paraffine, 10 per cent., and benzine, q. s. to moisten a pound of jute.

The Munich formula is carbolic acid, grammes 50; resin, grammes 200; glycerine, grammes 250; and alcohol, grammes 550, for one pound of jute.

He also exhibited two kinds of new material for surgical dressing. First, Von Bruns' gauze, made by the addition of castor oil. The formula is resin, grammes 400, carbolic acid, grammes 100, castor-oil, grammes 80, and alcohol, *two* litres.

This material can be made by any general practitioner, and clinically, works very well. It can be kept on hand in solution. The other material was jute, containing *chloride of zinc*, and made after the following formula of Burdick: Chloride of zinc, 100; water, 1,000; and jute, 1,000. The conclusion from the analysis is that new carbolized material can be easily made, that it should be made in small quantities, and not kept on hand too long, and that all the materials, when prepared, should be tightly wrapped in rubber cloth and kept in boxes in a cool place.

The Society then proceeded to the transaction of miscellaneous business.

Correspondence.

DOCTOR'S BILLS.

To the Editor of The Medical Record:

Sir:—I am sure that I am not the only one of your numerous readers who was interested in your editorial on doctor's bills. I may say painfully so, at this season, when I look over my ledger preparatory to sending out my bills. Every practitioner meets with the demonstrative patient whose ardor for paying disappears with his tears; but he should be met in but one way. It is cruel to deny those good people a chance to acknowledge such indebtedness. By a little management, I have recovered fees which would have been irretrievably lost. But every practitioner must know how to do this in his own way, and it is unnecessary to go into any details about the matter. In fact, it is not my purpose to refer to that particular part of your remarks, but to allude more particularly to the careless manner in which physicians keep their accounts, and how indifferent they are to the collection of the smaller bills. You very truly say that our patients take the cue from us, and believe our services are of small account. Every one's experience in collecting bills demonstrates this, and we are to blame for it. There is generally a lack of exactness in rendering our accounts, which is unbusiness-like, and very often impresses the patient with the idea that our charges are arbitrary, whimsical, and unreasonable. We impress the patient with the idea that if he is rich we will make him pay roundly for professional services, and thus stand in our own light by making it appear that the rich are our legitimate prey. What is the consequence? We place a premium on dishonesty, and invite the best of our patients to plead poverty, to cry for mercy, and to feel that they must escape a trap we have laid for them. How often has it been said by our patients: "Doctor, I hope your bill will be light, for really I cannot afford to pay a large fee." In other words, he means to say that the doctor must not take advantage of him by charging him more than he would other people.

We, as a class, foster the belief that we are constantly watching to make the rich pay for the poor, and are constantly straining a point in favor of every one's poverty of which we have any suspicion. Between the two horns of the dilemma we lose the best part of our income. The rich steer clear of us, and the middling classes very often impose upon us. The latter have plenty of chances for doing this in applying at the dispensaries, or in getting the opinion of one of the "head doctors at the college." Now, this brings me to the main purpose of my letter, and that is the itemizing of our bills. I know that by some it would be considered undignified; but, after all, is it not business-like? We make each visit by itself, with an expectation of being paid for it, and if we keep each visit in mind when we render the bill, we are not so apt to lessen the amount, nor are we inclined to give the patient the idea that a few visits more or less are of no great importance. I am of the opinion that this lumping of bills is bad practice. No one can afford to do it, except such as our Pine Ridge friend, who is too successful and too busy to attend to such small matters. What is right one way is right the other. We should claim no more than our just bills, but we should insist upon having the full amounts for the same. If we were a little more particular in insisting upon these points, we would doubtless have less reason to complain of bad debts. Of course, some accounts must be missed *nolens volens*, but these can be reduced very much in number if we are in earnest in collecting our bills.

X.

New York, Jan. 5, 1880.

To the Editor of The Medical Record.

Dear Sir:—Will you allow me, in thanking you for your timely remarks on medical fees, to suggest that physicians send in their accounts monthly? I know the longer they are deferred the harder it seems to pay them. Then, again, attendance extended over a long period is apt to "mount up" very fast, and the longer it is allowed to do so the more surprised is the patient to find how large his bill is. It would be the same with his grocer's or his butcher's bills.

GRATUITOUS SERVICES TO CLERGYMEN.

To the Editor of The Medical Record.

Dear Sir:—I have read with much interest the correspondence on the subject of "Gratuitous Treatment to Clergymen," but think we fall short of our mark if such things are discussed in medical journals only.

The clergy do not see them there; and one reason why I think the abuse is continued, is because the clergy have not had their attention called to the subject.

I have taken the liberty of copying your editorial article of December 13th entire, and sending it to the *Churchman*, a publication which is largely circulated among the Episcopal clergy, with the request that it be printed in a current number. This will show those divines who read that paper how we feel on the subject; and, as I believe those men to be *gentlemen*, I think they will see the justice of the remarks that have appeared in medical journals concerning them, and will be ready to correct it. Now, I suggest that some other doctors, who are members of the other religious beliefs, send copies of the same editorial to the different religious papers, and thus our remarks will appear before the majority of the class we are trying to reach.

A one-sided argument never does any good.

MacP., M.D.

Minneapolis, Minn., Dec. 23, 1879.

CONCERNING NEGATIVE PRESSURE.

To the Editor of The Medical Record.

Dear Sir:—I desire to say a few words in response to Professor Garland's article on "Negative Pressure," published in the Record of December 27, 1879. Before making my criticism I wish frankly to acknowledge that Prof. Garland's assertion, made in criticism of a protest which I had made against the use of the term in question, in the Record of Sept. 27, 1879, namely, that I had "failed to understand the meaning of the term," is correct. I had assumed that the words were used in their ordinary sense. It was through my own carelessness that Dr. Garland's clearly-worded definition, given in his work on "Pneumono-dynamics," did not correct my misapprehension. This definition is as follows: "As I understand it, negative pressure is simply the scientific expression for the common term *suction*. It does not, however, imply anything as to the magnitude or intensity of any force, but simply designates the manner in which the force is applied. Suppose the planes A and B are placed in immediate contact with each other, to the exclusion of all intermediate air. Now, if an external force, or if an inherent, automatic force, act upon the plane A to remove it from B, then A is said to exert a negative pressure upon B."

Dr. Garland, in accordance with this definition, calls attention in his article to the fact that, in case of a suction-pump, the term *negative pressure* is applied, not to the atmospheric pressure, but to the force which elevates the piston. Now, the definition of *pressure*, quoted by him from Rankine, is as follows: "Thrust or *pressure* is the force which acts between two contiguous bodies, or parts of a body, when each pushes the other from itself." In his definition of *pull*, Rankine remarks that "the word '*pressure*,' although strictly equivalent to '*thrust*,' is sometimes applied to stress in general." It is only under this exception that the term *pressure* can be applied to a force *pulling* up a piston. This usage is not sanctioned by Webster or Worcester. Webster defines *pressure* as being "the action of a force against some obstacle or opposing force." To speak therefore of A as exerting *pressure* on B, whatever may be the adjective applied to *pressure*, is, it seems to me, to employ the word in a sense not justified at all by general usage in other connections. B is *not* "an obstacle or opposing force against which A is acting." On the contrary, A is being drawn away from B, or would be were it not for atmospheric pressure. This use of a word in a sense not only differing but diametrically opposed to its accepted meaning, does not seem to me to contribute to a "systematic and orderly arrangement of knowledge."

The use of the negative sign in an algebraic equation in ascertaining the resultant of opposing forces is, of course, allowable. But the use of the word *negative* as applied to a thing essentially positive when

the algebraic formula is out of mind, seems hardly conducive to clearness of statement. The words *operation* in English, *operation* in French and *Saugen* in German, express the idea in question without ambiguity. The term *evacuant-producing power* is perhaps still clearer. Where, then, is the necessity of using an expression so capable of misinterpretation as *negative pressure?* In spite of general usage, I fail to see that it is either desirable or scientific to use an expression one word of which (*i. e.*, negative) is employed merely in an algebraic sense, not in accordance with its ordinary signification, and the other (*i. e.*, pressure) in a sense which is in direct contradiction to its accepted etymological meaning.

Very truly yours,

R. VAN SANTVOORD.

66 WEST ELEVENTH STREET, Dec. 29, 1879.

THE "SUCCESSFUL PRACTITIONER OF PINE RIDGE" AND THE CODE.

TO THE "SUCCESSFUL PRACTITIONER" OF PINE RIDGE.

DEAR SIR:—Pardon a stranger for venturing to trespass upon your valuable time, but the benevolent tone of your communications to the medical press, and the wholesouled devotedness to the welfare of the profession which is evidenced therein, encourages me to write you. I want to say that I have considered your account of your professional life as very interesting and edifying. It is particularly fortunate that at this time you have given the profession such a glimpse of the "inwardness" of successful practice of the code. I have been practising a number of years in this place, and have always watched the course of practitioners of success with very earnest interest, have listened to their discourses and words with attentive ear, and have sought to be guided by their example as far as was revealed. The candor and honesty of your statements is so conspicuous, however, and the perspicuity of your discourse is such as renders your ideas and practice most forcible. It is rare that authors attain so full a grasp of the subject. I await with expectation the appearance of your work on "Abrasions," etc., as it will doubtless be reliable and full of valuable suggestions. I have no doubt I shall hear of its publication early and be able to avail myself of its ideas in good season; still, if you publish pamphlets, please do me the favor of a copy, and I shall thus be able to make early confirmations, when proper occasion offers, of the methods you find successful.

I have just referred to the perspicuity of your biographical sketch; I must mention, however, an incident that will show you that time is necessary for the proper application of the character and works of advanced men. When the first section of your sketch appeared I referred it to a medical friend who has flourished during nearly sixty summers of modest contentment, and commended it as an article of merit. When the second came to hand, I went to him with some degree of enthusiasm over the portrayal of your success and how it was obtained, and expected no little pleasure in our mutual admiration of the revelation of the autobiographer. I was cooled considerably to find that my senior friend had his attention altogether concentrated upon Dr. White and his want of knowledge of professional tactics. The surpassing skill with which his rival outshone him, did not attract his admiration at all. Well, I managed to content myself until the third chapter came, and the transcendent revelation therein announcing your new invention, the diaphragmatico-gastro-hepatic speculum combination, or something of that nature. Then the light of genius burst upon him, and he indulged in audible expressions of joy. He then found reperusal interesting and suggestive.

Another point before I close. When I was at the beginning of my medical life, I was greatly impressed with the beauty and convincing eloquence of the code of ethics, and had enough missionary spirit in me to plan making a translation thereof for use among the Indians. On engaging in the practical work of the profession, however, my time was so much taken up in efforts to make my living and in anxiety therefor, that I could not accomplish my plan. And then I found that there were serious difficulties in the conscientious practice of the code, at times, that convinced me that a translation of it would be of no use to the Indians unless a practical embodiment of its principles, in a biographical form, accompanied the text. While I have labored on in hope, and have selected one and another living exemplar as a fit subject for biographical accompaniment to the work, I have found the difficulties rather increased; and now that I have read your autobiography, I am convinced that a translation had better not be made yet. Until the Indian becomes more advanced the work would probably do more harm, by preventing a few "medicine men" from getting a living, than good. I have, therefore, given up my first idea, and if I find time to translate anything it would probably be your life and writings. Others who are familiar with European, Oriental, and Egyptian manners and tongues, will doubtless become early transcribers of your works therein. Meanwhile I am glad the record of your honest and successful effort appears in plain English. Your example and suggestions are calculated to assist many in overcoming those practical difficulties that the unenlightened follower of the code meets with in his competitive work. The principles and practice of business in medicine is the earnest study of

Yours very truly,

MEDICAL ASPIRANT.

WARE, MASS., Dec. 20, 1879.

New Instruments.

DESCRIPTION OF A NEW INSTRUMENT FOR INJECTING THE HERNIAL RINGS IN THE RADICAL CURE OF HERNIA.

By JOSEPH H. WARREN, M.D.,

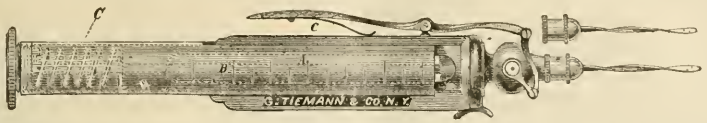
BOSTON, MASS.

THE instrument here figured consists of a barrel, A, holding about sixty minims. This barrel is of glass, accurately fitted within a cylinder of silver, which is fenestrated with two openings to present a view of the barrel and its contents. The barrel is graduated, each degree indicating ten minims. The piston, B, works by a spring, C, very tightly within this tube, so as to exclude all air possible. The lower end, D, of the piston is slightly concaved. At the bottom of the interior of the glass barrel is seen a ring, E, one-eighth of an inch in thickness, made of soft rubber, for an air chamber, with a hole in its centre for the exit of the fluid.

On the lower exterior end of the barrel will be seen

wo convenient semicircular handles, with the con-ave side roughened to give a firm hold for the finger nd thumb of the operator. In one of these handles, he one grasped by the thumb is the spring, c, con-rolling both the piston, B, and a valve, G. We thus ave perfect management, both of the amount of the luid to be injected, and of the time when it shall be njected.

The valve, G, is situated just below the bottom of



he barrel and rubber chamber, and is opened and hut by pressure on the spring, c. Below this valve s a diamond, or other hard stone, concaved to fit exactly the convex head of the needle which plays upon it.

The needles are flattish, oval in shape, and are wisted throughout their entire length. They are of hree sizes. No. 1 is one and a quarter inches in ength, size two and a half Amer. scale; No. 2 is one nd three-eighths in length, size two and three-quarters, Amer. scale; No. 3 is one and a half inches n length, and size three. It should be remembered hat, from their peculiar form and twist, they make n incision only about one-half the size of round needles which measure the same on the scale. The wist of the needles also varies. No. 1 is twisted to evolve once in penetrating one-fourth of an inch. No. 2 once in penetrating one-half an inch, and No. 3 once in penetrating three-quarters of an inch. I se No. 1 in operations on umbilical hernia and other ierniæ where the tissues are thin. It is therefore small, and has a quick twist because it is necessary hat the needle in penetrating should make a full evolution, so as to distribute the fluid on the parts o be irritated by the injection. No. 2 is for use in operating on the majority of small and recent her-iæ. No. 3 is for use on large and long-standing uptures, where the needle must traverse tissue gen-rally much thicker than in the other cases mentioned, nd often surrounded by adipose deposit. I wish to ay just here that the same principle of the twist can e applied to all trocars, aspirating needles, male and female catheters, tracheotomy tubes, canulas for in-ecting fistula in ano, and to sounds and dilators for stricture of the urethra and uterus. I may say, too, that these instruments thus improved can be ob-tained of the same manufacturer who makes this in-strument for the radical cure of hernia. The needle has a round shank, playing through a collar, H, which is attached by a screw thread to the neck of the barrel.

I have said that there was a rubber cushion at the bottom of the glass tube, A. This cushion remedies the defect common to hypodermic, as well as all other syringes, for it forms an air chamber which arrests the passage out of any air that may be in the barrel, and there is always more or less, and this would be injected with the fluid. It also acts very effectually in stopping the farther action of the piston after all the fluid has been injected.

The method of using the instrument is as follows: With the valve, G, closed, the needle is inserted in the fluid to be used. The valve is now opened by slight pressure upon the spring, c. The pressure being continued, the piston can be retracted and the barrel will be consequently filled with the fluid.

The valve is then allowed to close, and the instrument is charged for use. Having selected the most suitable point over the rings to be injected, we now thrust the needle slowly and gently, but at the same time firmly, through the integuments. During this act the needle revolves because of its twisted form. As soon as it has passed through the integuments, pressure is made upon the spring, c, which opens the valve, G, and allows the fluid in the barrel to flow as slowly and in such quantity as the operator may in any given case think necessary. The quantity used can, of course, always be known by the engraved scale on the barrel.

51 Union Park, October 2, 1879.

DRAINAGE-TUBE CARRIER.

Dr. John B. Hamilton, Surgeon-General of the United States Marine Hospital Service, has devised a simple and efficient instrument for placing drainage-tubes in wounds.

The instrument is one that is generally needed for the purposes indicated, as drainage-tubes are usually carried into place by forceps. In withdrawing the forceps, the tube is frequently drawn out with it.

The instrument consists of a stylet, with a hook at the end within a canula; the stylet is moved by a button over a side slot in the canula. A spear-head may be attached for use where it is desired to carry the tube into a cavity which has no external opening. It will be a necessary attachment in introducing a seton, or a drainage-tube through a flap after an amputation, or through the vagina in Douglas's cul-de-sac, after ovariotomy, or in course of treatment of pelvic cellulitis.

In using the instrument, the drainage-tube must be kept taut, so that when released, it will instantly, by its own elasticity, throw itself from the grasp of the stylet.

Collodion as an Application in Acute Rheumatism.—Dr. J. W. Reins writes to the *Western Lancet* that he has met with much success in the use of collodion applied to the inflamed joints in acute rheumatism. He paints the part four or five times a day.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 21st, 1879, to January 14, 1880.

Barrows, J. H., Capt. and Asst. Surgeon. Granted leave of absence for six months. S. O. 290, A. G. O., December 24, 1879.

Byrne, Charles B., Captain and Asst. Surgeon. Granted leave of absence for two months, with permission to apply for an extension of four months. S. O. 287, A. G. O., Dec. 20, 1879.

Havard, Valery, Capt. and Asst. Surgeon. His leave of absence extended one month. S. O. 91, Div. of the Atlantic, Dec. 22, 1879.

Hall, Wm. R., First Lieutenant and Asst. Surgeon. Granted leave of absence for one month, with permission to apply for an extension of three months. S. O. 180, Dept. of the Columbia, Dec. 5, 1879.

Vollum, E. P., Major and Surgeon. Relieved from special duty in connection with inspection of veterinary supplies, to resume his station at Jefferson Bks, Mo. S. O. 291, A. G. O., Dec. 29, 1879.

Forwood, Wm. H., Major and Surgeon. Assigned to duty as Post Surgeon at Ft. Omaha, Neb., relieving Asst. Surgeon R. Barnett. S. O. 121, Dept. of the Platte, Dec. 29, 1879.

White, R. H., Capt. and Asst. Surgeon. Relieved from duty in Dept. of Texas, to proceed to New York City, and report by letter, upon arrival, to the Surgeon-General. S. O. 293, A. G. O., Dec. 29, 1879.

Taylor, R. D., 1st Lieut. and Asst. Surgeon. To report in person to Comdg.-General, Dept. of the East, for assignment to duty. S. O. 292, A. G. O., Dec. 27, 1879.

Hall, Wm. R., 1st Lieut. and Asst. Surgeon. Relieved from duty in Dept. of the Columbia, and, upon expiration of his present leave of absence, to proceed to New York City, reporting his arrival, by letter, to the Surgeon-General. S. O., 293, A. G. O., Dec. 29, 1879.

Appel, D. M., 1st Lieut. and Asst. Surgeon. Relieved from duty in Dept. of the Missouri, and, upon expiration of his present leave of absence, to proceed to New York City, and report by letter, upon arrival, to the Surgeon-General. S. O. 293, C. S., A. G. O.

A Modest Contributor.—We have received the following amusing note regarding a contribution to our columns:

"Dear Sir—Two weeks ago I mailed to your address a short sketch, regarding the properties of ——, to prevent misleading young physicians in their observations and practice. I see you have not published it. I think my observations of 100 cases, and for three to four years, are just as valuable to the profession as Dr. Rokitansky's or Dr. Schiller's. Besides, as a reader of your journal for several years, you should treat your subscriber with more consideration. I think so! I am, sir, truly yours."

[We are happy to say that we just saved ourselves by accepting the little note for publication as an item. If we had known its importance before, we would have published it at once. We are willing to give every consideration to such contributors, if for no other reason than to humble Rokitansky and other great men.—Ed.]

Medical Items and News.

Contagious Diseases — Weekly Statement — Comparative statement of cases of contagious disease reported to the Sanitary Bureau, Health Department for the two weeks ending January 3, 1880.

Lumbo-Colotomy for Non-Malignant Disease.—The following case was communicated to Dr. L. A. Sayre, of this city, and is by him kindly placed at our disposal. "I see in the Medical Record of last week the report of a case of 'lumbo-colotomy for *non-malignant* disease,' made by Dr. Post, before the Academy of Medicine, November 20th; and the remarks made by yourself and others upon the case brings to mind a case occurring in my practice a few years ago, which may be of some interest to you, so I will give you a short account of it. The patient was a young man aged about 20, always healthy, and of good family history. Sent for me in the fall of 1873, on account of a severe pain in his bowels, with inability to get a movement; stated he had taken sixteen pills without effect, but they rather made him worse. Upon examination, I found a fulness in the right iliac region, with a good deal of tenderness; an oblong tumor of the cæcum; vomiting, hiccough, and all the other symptoms of obstruction of the bowels. He went along, getting worse for over two weeks, when he had become so much depressed that it seemed he would soon succumb. I determined to make an artificial opening for the fæces, as nothing had passed his bowels excepting a little bloody mucus since taken; and, upon examining the right lumbar region, discovered a point of some fulness, through which I proceeded to cut directly down to the gut, which I found greatly distended; and upon opening it there was a large discharge of liquid fæces, gas and some bloody pus. The artificial anus was kept open for about two weeks longer, when he had a passage by the natural way from the bowels, which was the first since taken sick, and in the passage was a portion of the intestine about eight inches in length. He continued to have evacuations through both channels for some time longer; but the artificial one gradually diminished, and finally healed up entirely, and he entirely recovered his health, and is now a strong, healthy man, employed as a conductor on our railway."

A Correction.—In the report of the Preston Retreat, in your issue of Nov. 29th, there is a typographical error which needs correction. Under the head "Closure of the Vulva for Vesico-vaginal Fistula," the first line should read "In incurable cases etc.," instead of "*in curable cases*," as it now stands.

Formation of Artificial Vagina.—In April, 1878, a young married woman, aged 22, was admitted to the Female Mission Hospital, Ajmere, India, asking relief for occluded vagina. She stated that she had always menstruated regularly, but that, on being

married, it was found that she could have no connection with her husband. She had been badly treated by him and others in consequence.

On examination by Dr. John Hubbard, the attending physician, no trace of a vagina could be found. At the upper part of where it should have been, a pouch-like projection was felt, which proved to be the urethra greatly dilated. Examination by the rectum showed that there was a uterus which communicated with the urethra, thus explaining how she had been able to menstruate.

An operation was decided on. An incision was made in the tissues between the urethra and rectum, a staff having been introduced into the bladder. By cutting and tearing, a channel was easily made to the uterus. After the operation this was kept open by plugs of lac. Within two weeks the patient was discharged with her new vagina. She returned in a few months in great glee, saying that she was pregnant. The child was a small one, and was delivered in safety.—*Brit. Med. Journal.*

Vitality in Decapitated Heads.—A criminal was recently guillotined in Paris, and five minutes after the execution his head was turned over to Dr. E. Decaisne, in order to test whether, as had been alleged, there was any vitality still in it. The report of the experiment in the *Bulletin de l'Académie de Médecine* states: "We have ascertained, as far as is humanly possible to do so, that the head of the criminal in question had no semblance whatever of the sense of feeling; that the eyes had lost the power of vision, and, in fact, that the head was perfectly dead to all intents and purposes." The tests made were the application of irritants, noises to the ear, and lights before the eyes.

Increase of Infectious Diseases.—The Connecticut State Board of Health has issued a circular calling attention to the increasing prevalence of small-pox and measles. The former disease has prevailed in the principal cities of Europe since August last, and 214 deaths have occurred in Paris from the disease. It has also appeared at Montreal, St. John, Havana, and Matamoros, and more recently Philadelphia, Washington, San Antonio, New York, and New London have reported deaths from the same cause. The importation and interstate shipment of rags has been proved in some cases to be the carrier of the poison; but there is a tendency also for small-pox to appear in widely separated places, and early precautions are therefore advised. It is recommended that the common councils of the various cities pass an ordinance requiring all school-children to present a certificate of vaccination.

Contagiousness of Post-nasal Catarrh.—Dr. William R. D. Blackwood, in the *Philadelphia Medical Times*, writes that it is his belief, from close observation, that post-nasal catarrh is under certain conditions contagious, even when positively non-syphilitic. He has repeatedly seen the disease occur in newly married persons, and where children previously healthy had slept with those thus affected. In all such instances there was no hereditary tendency, nor were other members of the family affected.

University of California.—The medical department of the University of California several years ago adopted a three years' graded course for its students. In its just published annual announcement we see that it has taken a further step toward securing a higher education by requiring a preliminary examination for matriculation. At the last commencement of this college, Nov. 7, 1879, the degree of M.D. was conferred on thirteen graduates.

Mr. Curling, the London surgeon, who has been in active practice for upward of forty years, has now retired from the council of the College of Surgeons, of which he has been member and president, and he is soon to retire from practice altogether.

Dr. Seaton, who has been for four years medical officer of the Local Government Board of England, has retired, on account of ill-health.

Harvey's Treatise on the Heart and Circulation, *exercitatio anatomica*, has for the first time been translated into French.

Slow Pulse.—A number of cases of notably slow pulse have been reported in the *British Medical Journal*. Mr. Noble relates the case of an old gentleman of ninety-six, whose pulse was only 36 per minute. Mr. Edw. Garraway tells of a patient of his, an old woman aged eighty-three, whose pulse was 25. In a case related by Mr. R. Park, the pulse varied between 32 and 36. A gentleman aged thirty-eight had a pulse of about 40. He was in good health, and had no other physiological peculiarity. A gentleman aged sixty-seven had a pulse of 32, which sometimes dropped to 28. A woman aged sixty-nine had a pulse of 30 or 36. In these two last cases there were occasional symptoms of dyspnœa, syncope, and cold extremities. The pulse, when by any cause greatly accelerated, became intermittent.—*Brit. Med. Journal.*

Litholapaxy.—Sir Henry Thompson recently performed the operation of litholapaxy, at the Necker Hospital, Paris. The patient was a man, aged 54, who had already been operated on twice by lithotrity. The operation on the present occasion lasted sixteen minutes. The patient at last accounts was doing well.

Intra-uterine Vaccination.—Cases have been related of women who were vaccinated while pregnant—the infant, subsequently born, not being susceptible to the vaccine virus. It appeared possible, therefore, that in some cases genuine intra-uterine vaccination had taken place. Other cases, however, have been reported which prove that this non-susceptibility does not always occur. One woman had the small-pox while eight months pregnant: her child was afterward vaccinated and showed a well-marked pustule of vaccinia.—*Brit. Med. Journal.*

The Boston Medical and Surgical Journal for 1880 appears in a new dress. It is in quarto form, and enlarged in size. The new make-up is a great improvement, and is an indication of prosperity which the high standard of the journal richly deserves.

The Pancreatic Ferment.—Dr. Wm. Roberts, in an article upon the digestive ferments describes a way of administering the pancreatic ferment so that it will act effectively. Pancreatic preparations are more powerful than those of pepsin, and digest with great energy starch, albuminoids, and fat. Unfortunately, however, they act only in alkaline media, and the acid gastric juice neutralizes and digests them before they can reach the intestine. In order to prevent this, Dr. Roberts gives the preparation two or three hours after each meal, guarding it with an alkali. As the gastric digestion is nearly at a close at this time, the pancreatic ferment is supposed to be carried safely through the stomach. Dr. Fothergill, who describes this plan in the *Phila. Medical Times*, is full of admiration for its great ingenuity, and of praise for the prospective

beneficial it will secure. We do not share the raptures. It remains to be proved that the trey-in gets safely through the stomach, and that its alkaline body-guard will not excite enough gastric secretion to destroy it. Further, intestinal indigestion is comparatively rare, and in dyspepsia the worst distress is in the hours directly after eating. A medicine not given until the pains are over cannot become very popular. But the theory is a beautiful one, and evidently has fascinations to the scientific therapeutist which the lively imagination of Dr Lothergill could not resist.

Damages for a Doctor.—Dr Phillips, a London physician of large practice, sustained injuries from an accident on the Southwestern Railway, which destroyed for a time, and perhaps permanently, all possibility of earning a professional income. He sued the company, and got on the first trial £7,000 damages. Being unsatisfied with this, he sued again and got £17,000. This is probably the largest sum ever awarded by a jury for personal damages.

The Measles continues to be unusually prevalent in the city. The death-rate is about .8 per cent., which indicates a not very severe type.

Death of Dr. Robert C. Cone.—Dr. Cone died at his residence in this city, Dec. 21st. He had been an active practitioner here since 1865.

Benzoate of Soda.—Dr. Bernard Tauber, of Cincinnati, Ohio, writes: "This drug seems to be the latest "en vogue" remedy for the treatment of diphtheria, phthisis, etc. For the last three to four years, in about one hundred cases of ozæna and diphtheria, I have used, locally and constitutionally, in weak and strong solutions, benzoic acid, thymol, and thymic acid. The results were the same, at least not better, as when a solution of carbolic acid was applied."

The Care of the Insane.—A meeting was held at the residence of Dr. C. R. Agnew, January 6th, to hear the State Commissioner of Lunacy, Dr. John Ordronaux, deliver an address on the subject of Lunacy Reform. A large number of distinguished guests were present, representing the medical, legal, and clerical professions. Among these were Rev. Drs. Thos. S. Hastings, Howard Crosby, John Hall, Armitage; Judge Curtis; Drs. A. C. Post, Dalton, Sims, Roosa, Loomis, Nichols, Shaw, John P. Gray, A. E. Macdonald, George M. Beard, Dana, W. H. Draper, Shrady, Prof. Chandler, and a number of others. Judge Curtis presided. The address of Dr. Ordronaux was listened to with much attention, and was followed by brief remarks from Dr. Agnew.

New York Neurological Society and the Report of the Senate Committee.—At the stated meeting of the New York Neurological Society, Tuesday evening, January 6th, a report entitled "An Answer to the Document of the Senate Committee on Public Health concerning the alleged Abuses of Insane Asylums," was read. It contained a vigorous denial of the conclusions in the Senate Committee's report, as well as a number of accusations against the fairness of that committee. It was accompanied by a number of documents substantiating the statements made. As this report will soon be published in detail, a fuller account of its contents is postponed.

Treatment of Alcoholism.—The results of an analysis of 125 cases of alcoholism treated in the Mercy Hospital, Chicago, have been presented by Dr. E. C. Hehn, in the *Chicago Medical Journal and Examiner*.

Most of the cases presented symptoms of excitement, ranging from restlessness and insomnia to delirium tremens.

These were deprived at once and entirely of alcohol, and put upon potas. brom., gr. xx., and tr. digitalis, ℥ v., every three hours. If this did not produce quiet, chloral hydrat., gr. v. to xx. were given every half hour until three doses were taken. Chloral in 3ss. doses had produced very serious symptoms.

In cases where there was much gastric disturbance, the treatment was supplemented with carbolic acid and tincture of gelsemium in a little paregoric.

The results of the above treatment have been uniformly good, the patients being generally cured in six or seven days.

Injury of Eyes from Chloral.—Dr Charles J. Kipp, of Newark, N. J., writes under the above heading: "I find in the last number of the Record a letter from Dr Felton, in which he relates two cases (apparently from hearsay) of 'permanent weakness' of the eyes, following an acute inflammatory attack, brought on by the use of small doses of chloral continued only for a few days. He concludes his communication with the question, 'Has chloral ever before been known to produce a similar attack?' In answer to this, I would state that some years ago I saw several persons suffering from affections of the cornea, who assured me that their eye-troubles came on shortly after taking chloral. Thinking that there might possibly be some causative relation between the eye-disease and the drug, I examined a large number of individuals—inmates of lunatic asylums and others—who were habitually taking chloral in pretty large doses, but found no more eye-trouble amongst these persons than is found amongst people taking other medicines, or none at all. The conclusion I arrived at, at the time, was, that there was no good reason to assume that chloral produced eye-disease of any kind, and I have had no cause to change my opinion since then. With regard to the cases related by Dr. F., I may be permitted to remark that he has failed to furnish any evidence whatever in support of his opinion."

Committee on Organization of a State Lunacy Commission.—The committee appointed for this purpose, at the recent meeting at the Cooper Institute, is as follows: Mr. Wm. C. Church, Chairman; Hon. Dorman B. Eaton, Mr. Chas. E. Whitehead, Dr. George M. Beard; Dr. E. C. Seguin, Secretary. Associates—Mrs. Abby Hopper Gibbons, Miss A. A. Chevallier, of Boston. Three meetings of the committee have already been held, and considerable progress is being made in the work.

Original Lectures.

A CLINICAL LECTURE,

DELIVERED AT THE PENNSYLVANIA HOSPITAL, PHILADELPHIA,

BY J. M. DA COSTA, M.D.,

PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE, AND OF CLINICAL MEDICINE IN JEFFERSON MEDICAL COLLEGE.

(Reported for THE MEDICAL RECORD.)

I. DILATATION OF THE STOMACH.
II. BRIGHT'S DISEASE AS A RESULT OF EXPOSURE OCCURRING IN A MALARIAL SUBJECT, AS DISTINGUISHED FROM THE SO-CALLED MALARIAL BRIGHT'S DISEASE.
III. ACUTE TUBAL NEPHRITIS ENGRAFTED UPON A PREVIOUS CHRONIC CONDITION.

THIS is one of those cases of a chronic character which seem very easy to dispose of at first, but which, upon longer observation, turn out to be very difficult to treat successfully.

The patient is a man some fifty-five years of age, and by occupation a car-driver. He says that he has never been more than a moderate drinker. Two years ago he began to be dyspeptic, and lost his appetite. He found himself also obliged to urinate frequently at night. There was no dropsy apparent upon admission, but he vomited frequently, and was, in fact, one of those most unfortunate of beings, a wretched dyspeptic. His tongue was thickly coated, and his urine alkaline and phosphatic, but free from albumen and sugar. The abdomen was distended, and the epigastrium tender. He was, in other words, flatulent and constipated, with symptoms of marked organic dyspepsia.

We kept him in bed for a time and gave him complete rest, and set ourselves at work to find out the cause of his dyspepsia. Perhaps the numerous and painstaking examinations which were made in the wards can be usefully repeated to some extent in your presence this morning. Let me examine the patient as if this were the first time I had seen him.

His tongue is somewhat less coated than it was, but is still far from clean. The resident tells me that he still vomits once in a while, that is, once in every two or three days. These spells of vomiting occur generally at night, or near the end of the day. At such times the contents of the stomach come up in large quantities—sometimes the vomit appears to represent the whole of several meals. This vomit has a thick froth on the surface, which smells and looks like the froth of beer or yeast, and leaves a heavy deposit on the bottom of the vessel.

"Have you ever any pain in your stomach?"

"Yes, I have cramps in my stomach occasionally, but not often."

These cramps are generally at night, and come from over-distention of the stomach. They were very much more marked just after he was admitted than they are now. There has, upon no occasion, been any vomiting of blood.

To what does all this point? It points unquestionably to some organic disease of the stomach. To what organic disease does it point—to cancer? The patient is at the cancerous age, and the vomiting at night looks very much as if there were some mechanical obstruction, such as cancer, to the free passage of food into the pylorus. I examine the region of the stomach, and particularly its pyloric extremity, for a tumor, but can find none.

I percuss the region of the stomach, but can detect no dulness. On the contrary, I find the stomach tympanitic as far down as two inches below the navel. There is plainly a very unusual increase in the size of the stomach. There is no tenderness on pressure, no spots of soreness, no pain in the back. These points have a direct bearing upon the existence of ulcer or cancer. These are negative symptoms.

Under my supervision, the resident physician has made a most careful microscopical examination of the vomited matters, and, just as we had expected, he found a great many bodies like this figure, which I outline on the blackboard, floating about in the vomit—the so-called *sarcinæ*—a peculiar vegetable fungoid growth, described by Goodyear, and almost always associated with this yeasty vomit—this obstinate dyspepsia, and this dilated condition of the stomach. We have then here one of those rare cases of dilated stomach with narrow pylorus, unattended by either ulcer or cancer.

What are my reasons for thus positively excluding these two conditions? First, as regards my reasons for determining upon the existence of dilatation, they are: (1) because percussion shows an unusually extended area of tympany; (2) because a yeasty vomit containing sarcinæ is very apt to be present in dilatation of the stomach whether from cancer or any other cause; (3) on account of the way in which the vomit occurs, the accumulated results of several meals being cast up at a time.

My reasons for excluding cancer: (1) the absence of pain upon pressure; (2) the absence of any tumor; and (3) the absence of blood in the vomit.

My reasons for excluding ulcer: (1) the absence of pain after meals; (2) the absence of hemorrhage; and (3) the absence of points of local tenderness.

What has our treatment been? Since I have had charge of the case, I have treated the patient with bismuth, giving him gr. xv. between meals, and gr. x. of pepsin at meal-time. At the same time we have regulated the patient's diet, and attended to his bowels. We also have given him gtt. x. of the tincture of nux vomica before meals, with evident benefit. His tongue is cleaner, and he has gained flesh. To modify the process of fermentation in his stomach, he has been taking gtt. i. of the concentrated carbolic acid diluted with water and glycerine, once a day. His diet is chiefly fluid, consisting mainly of milk, oyster broth and beef-tea.

Shall we continue this treatment, now that we thoroughly understand the case, or shall we modify it? The same dose of bismuth shall be continued; so, too, with regard to the small doses of nux vomica before meals, and of pepsin with meals.

But we do not seem to be fulfilling the indication of checking fermentation, or doing anything to reduce the dilatation of the stomach. This brings us to the question of how to check the multiplication in the stomach of these agents which are associated with the fermentation. The best means at our command for accomplishing this end are sulphurous acid, the sulphites, and carbolic acid. In this case I shall order gr. ½ of carbolic acid, four times a day, in glycerine and water, and if this does not put a stop to the presence of sarcinæ, we shall have to resort to sulphurous acid or the sulphites.

Upon several occasions, in cases such as the present, I have made use of the German plan of washing out the stomach, and in so getting rid of the foul secretions. In this manner I have in several cases

effected an actual cure. The treatment by washing out the stomach is very annoying, but also in some cases very successful. I will perform it at your pleasure once to-day.

Washing out the stomach in chronic cases of dyspepsia, and particularly in those cases in which that organ is dilated, is a plan of treatment that, while it is not altogether new, may still be said to be so, since it has only become a regularly systematized form of treatment since Kussmaul introduced it.

The object aimed at by this method of treatment is to get rid of the large amount of fermented matter remaining in the stomach—matter which cannot otherwise be gotten out of the organ, and which, remaining in it, impairs digestion, ferments, and makes the patient's life wholly miserable, while it at the same time weakens the system and increases the dilatation of the stomach.

Simple lukewarm water was first employed for this purpose, but subsequently weak alkaline solutions of carbonate of sodium were tried. This latter medium is that recommended by Kussmaul.

In no instance should the operation of washing out be performed more than once a day, and, when the case is not a bad one, once in two days will be sufficient. The best time for the operation is in the morning.

The plan of the operation varies. Some clinicians use the siphon arrangement, while others prefer the ordinary stomach pump. There is not much difference between the two, except that the siphon is more convenient and is not apt to suck the mucous membrane of the stomach into the holes of the tube, as happened in one published case in which the stomach-pump had been employed.

The patient will now be put upon his side, and the assistant will perform the operation of washing out the stomach in your presence, in just the same manner in which it has been done in the wards.

All that is necessary when the siphon is used is a tin vessel, an elastic tube, and an ordinary stomach-pump tube. When the tube has been inserted well into the stomach, the vessel containing the alkaline solution is held above the patient's head. You see that the liquid flows in rapidly—is now all gone—but the liquid does not flow back out of the tube as easily as it usually does. Probably there is some hard morsel of food clogging up the tube. This accident, or rather its possible occurrence, is the only reason why the stomach-pump is preferred by some. Its advocates hold, and with reason, that it is not possible for the tube of the stomach-pump to become clogged with food-morsels.

I think that, in future, I shall use the stomach-pump for this purpose myself, instead of the siphon arrangement. The operation is at best such a disagreeable one that it ought never to be undertaken rashly.

The conclusions which I have reached with regard to this operation of washing out the stomach are: (1) that it is an operation to be restricted to a particular group of cases—those in which we have some obstruction at the pylorus, with dilatation of the organ, so that the contents of the stomach are not readily passed out of it; (2) that if, accompanying the dilatation, there be structural disease of the stomach, such as cancer, washing out the stomach rarely does good, except it be to get rid of accumulations which cannot otherwise be removed.

Have I ever known of any good results following its use, where the cases were suitable ones for its employment? Admirable results. In such instances I regard it as being the best method of treatment at our command. Even in one case of ulcer of the stomach in which cicatrization has now occurred, and where there was constant vomiting and great emaciation, the patient made a slow but sure recovery under this plan of treatment, in conjunction with a carefully regulated diet.

Are there any other means to assist us in the treatment of the conditions you will, no doubt, and with perfect propriety, inquire. Nux vomica is a very important adjuvant. At the same time the diet must be regulated. Small quantities of solid, and not too much liquid food, must be given. If the fermenting contents of the stomach cannot be gotten rid of, and if you do not wish to make use of the washing-out process, a brisk cathartic will often be found to be of great assistance. In this way you are enabled to cause the mass lying in the stomach to pass out, and on into the bowel. Indeed, in all cases of dilatation of the stomach an occasional brisk purgative will be found to be a much better method of treatment than the old routine plan of administering emetics. The act of vomiting is always more or less exhausting, and in cases of great dilatation of the stomach it is often a matter of great difficulty to excite vomiting by any amount of emetics, since the muscles of the stomach, being so distended, are slow to react to irritants.

[The patient was brought before the class a few weeks later, and presented the following conditions: the vomiting had stopped entirely; the natural powers of the stomach had been so far restored that the patient was able to digest a moderate meal without any great inconvenience; his tongue was much cleaner, and his stomach, upon percussion, showed a well-defined decrease in the amount of dilatation.

As the vomiting began to stop, the sarcinæ in the matter vomited gradually disappeared. Dr. Da Costa attributed this decrease in the number of sarcinæ partly to the washing out of the stomach, and partly to the remedies employed to stop fermentation. These remedies consisted at first in one grain of concentrated carbolic acid, well diluted, and, later, in f. ʒ i. of sulphurous acid, in water, thrice daily.

It was thought that there was no longer any necessity for washing out the stomach (the man had received so much benefit from this washing that he grumbled considerably when the order was given to discontinue it), but that the patient should take ten drops of the tincture of nux vomica thrice daily, and should be allowed a little more varied diet, a small amount of sulphurous acid being given occasionally after meals. The bismuth had been long discontinued.]

BRIGHT'S DISEASE AS A RESULT OF EXPOSURE, OCCURRING IN A MALARIAL SUBJECT, AS DISTINGUISHED FROM THE SO-CALLED MALARIAL BRIGHT'S DISEASE.

The second case which I show you will be in some respects a continuation of some remarks made at the end of my last clinic on the subject of Bright's disease, except that we have to-day an illustration of the disease due to a different cause, and presenting several peculiarities with regard to pathology and treatment.

T. F——, æt. 46; has always been a healthy man until last August, when he had chills which were at first quotidian and then tertian, which continued a month in spite of treatment, and which have since recurred irregularly. The week before the patient's admission to the wards he had a very heavy chill, which recurred every day, and lasted an hour at a

time. These daily chills were followed by fever and sweating. There was, in fact, a very marked malarial impression. Three weeks ago, after a heavy chill, which was followed by sweating, the man exposed himself. This exposure was followed by puffiness of the face, and then, in the course of three or four days, by a moderate amount of anasarca. The urine became dark-colored and scanty. There was, however, no headache, vomiting, or pain in the back. Upon admission the man was very ill. His whole body was œdematous, scrotum included. There were some excoriations on the front aspect of the legs, from which serum exuded. The patient at the same time had the most decided evidence of the malarial cachexia written on every feature of his face. His spleen was somewhat enlarged, and the area of liver dulness was increased.

What was the cause of the dropsy? An examination of the urine answered the question for us at once. Its specific gravity was 1022, and it was heavy with albumen. The urinary salts were found to be normal. Microscopic examination of the urine showed the presence in it of red blood-corpuscles, and of renal granular epithelium, together with hyaline and small granular casts. Two days subsequent to the patient's admission he had another distinct outbreak of the malarial element, attended with a temperature of 105° during the first chill, of 97° during the intermission, and of 102° during the second chill. After this attack the patient was put thoroughly under the influence of quinia, and had no further malarial outbreak, although the cachexia still remains.

The case is very plainly one of Bright's disease, complicated with malaria, and the only remaining question is whether the Bright's disease has been due to the malaria, or whether it has only come on in a malarial subject, and has been really brought about by exposure to cold and damp.

Looking carefully at the record, and taking all the circumstances of the case into account, I have reached the conclusion that it is one of acute Bright's disease coming on in a subject whose system was weakened, and who was, therefore, to a certain extent, predisposed to the disease. It is not what is usually known as Bright's disease from malaria.

I will thus sum up for you the progress of the case: After the first few days there was no further febrile exacerbation. The temperature remained low, ranging from 97°–97½°–96°, being at times, in fact, a little lower than normal. You can still note the powerful malarial impression in the altered hue of the patient's face, which, by the way, is a very typical face.

I will see whether the internal organs have undergone any change. Percussion shows me that the splenic dulness has decreased by at least a finger's-breadth. It now barely extends down to the last rib. The liver dulness is now entirely normal. There is no dropsy in the abdomen or legs. What about the kidneys? The kidneys are vastly improved. There is now no blood in the urine, and only the merest trace of albumen and hyaline casts.

This brings us to the consideration of the question of diagnosis, and you will, no doubt, wish to know my grounds for regarding the case as one of acute tubal nephritis, coming on from cold and exposure in a person weakened by malaria, and not as a case of the so-called malarial Bright's disease. I have seen a large number of cases of Bright's disease following malaria, and am therefore moderately familiar with the disease. By malarial albuminuria I understand a condition characterized by albumen in the urine, with granular and hyaline tube-casts coming on slowly, associated with dropsy, and as gradually passing away. In the long run, and with proper treatment, such cases usually recover. Their very essence consists in their gradual development, with impaired blood, dropsy, and bloody urine. Such cases have no acute stage such as was present in this instance.

The prognosis is even more favorable in this case than in those of malarial Bright's disease. [The patient left the hospital entirely well.]

In what has our treatment consisted? We have kept the patient strictly in bed, have given him an occasional purgative, and for a few days kept him under heavy doses of quinia. The purgative used was gr. ½ of elaterium. As the dropsy seemed to be somewhat slow in disappearing, we gave him occasionally doses of the fluid extract of jaborandi, which produced free sweating. We soon reduced the dose of quinia from twenty to eight grains daily. With the hope of producing diuresis, we at first employed Basham's mixture, but as its usual happy effects did not seem to follow, we gave the patient instead gtt. xx. of the tincture of the chloride of iron thrice daily, and gr. xx. of the acetate of potassium and a wineglassful of the infusion of broom four times a day. The latter drugs proved valuable diuretics in the case. This treatment, as it has been successful, shall be continued. The dose of the iron shall be increased to xxx. gtt. thrice daily, or rather he shall be given this form of iron every other day, and on the alternate days we will give him a hypodermic injection of gr. iij. of the ammonio-citrate of iron dissolved in water, which plan of treatment I have often found to be followed by the most beneficial results. In only one instance has such an injection been followed by abscess and hardening of tissues. We will keep up the dose of broom for some time yet. Together with this medicinal treatment, the patient is getting good, nourishing diet, and we will still insist upon his spending the greater part of the day either in bed or on a couch. We will not allow him to go out of doors at all for some time, for fear of his catching a fresh cold. [This patient left the hospital shortly afterward, entirely well.]

ACUTE TUBAL NEPHRITIS ENGRAFTED UPON A PRE-EXISTING CHRONIC CONDITION.

You remember my calling your attention, at a preceding clinic, to a case of Bright's disease in a boy of seventeen. You will also, no doubt, remember that I told you that the case, in its then aspect, was an acute one, but that the acute attack had probably been engrafted on a previous chronic condition. When you last saw the patient he was very ill, but he has improved very much, so much so that you will hardly recognize him as the same person. His improvement has been solely due to our steady adherence to a plan of treatment consisting in an occasional vapor-bath, a dose of elaterium now and then, and in keeping the skin and kidneys acting by doses of half a drachm of the fluid extract of jaborandi thrice daily for ten days at a time. To these items we added a plan of treatment which I have pursued very much of late, namely, the use of moderate doses of quinia, to counteract the depressing influence of jaborandi upon the circulation. I have found that by giving a certain amount of quinia with the jaborandi I obtain its valuable diuretic influence without the depression which follows large doses of it given alone.

You see that the dropsy has entirely left the face, except in the neighborhood of the patient's eyes. There is only the merest trace of abdominal dropsy. The urinary secretion has increased from f ℥ xij to f ℥ xxxvj daily. It is, in fact, a little more copious than we care to have it. The amount of albumen has so far decreased that it does not at present form more than one-fourth the bulk of the urine in the test tube. Since the dropsy has disappeared and the secretion of the kidneys has been freely established, we have stopped the jaborandi and placed the patient on gtt xxx of the tincture of the chloride of iron, four times a day, with an occasional purgative. Having got rid of the renal dropsy, we shall further improve the condition of the kidneys and lessen the albuminuria by means of the iron. I think that this patient will soon be able to leave the hospital almost entirely recovered. You may look upon it as a very fair illustration of an acute attack engrafted upon a previous chronic condition.

Original Communications.

FRACTURE OF THE HUMERAL EPIPHYSIS IN OLD DISLOCATIONS OF THE ELBOW.

By THEODORE A. McGRAW, M.D.,

PROFESSOR OF SURGERY IN THE DETROIT MEDICAL COLLEGE.

The few cases of unreduced dislocation which I have seen have resulted in great and permanent disability.

The inability which almost invariably accompanies this injury to flex the forearm within an angle of 120° is in itself a great inconvenience.

Patients with backward luxation of the elbow-joint can neither feed nor dress themselves, nor comb their own hair, nor even write, except in a most constrained posture. I cannot understand, therefore, the timidity with which Hamilton, in his famous work, approaches this subject, for while he quotes some cases of old dislocations in which he attempted, with varying success, the replacement of the bones, he records many others in which the disability was very serious, and in which he advised non-interference.

It has seemed to me that so grave a disability should warrant almost any procedure which would offer hope of improvement, and it was with that feeling that I proceeded to operate in the case I am about to relate: A little girl of nine years fell and dislocated her right elbow. The irregular practitioner who was called upon to attend her failed to recognize the trouble, and treated the case as one of fracture with the arm in extension.

The accident occurred on October 2, 1877. Nine weeks afterward, Drs. Taylor, of Mt. Clemens, and Brownell, of Utica, saw the child, recognized the nature of the injury, and made a vain attempt at reduction. Six weeks later, and fifteen weeks after the reception of the injury, the child was brought to me for treatment. On examination I found the arm nearly extended. There was limited motion at the elbow, but flexion caused pain and had to be discontinued when it had reached an angle of 120°.

On the 26th of January, assisted by Drs. Brownell, Gowan, Reynolds, and others, and in the presence of my medical class, I had the child anæsthetized and attempted the reduction of the dislocation.

I first broke up the adhesions and tried the ordinary methods of reduction by manipulation. These failing, the pulleys were applied and extension made to the utmost practicable extent in every position of the arm. I then divided the tendon of the triceps subcutaneously and applied the extending force until motion in every direction seemed absolutely unrestricted, and yet, though every obstacle had apparently been ruptured, the luxation could not be reduced. During the manipulation something suddenly gave way and the deformity disappeared, and I thought for the moment that I had achieved success, careful examination showed, however, that the old abnormal relations of the olecranon and the condyles still persisted, and further investigation revealed a fracture of the humeral epiphysis and a displacement of the epiphysis forward upon the shaft in such a way as to permit of easy flexion of the elbow and an apparent disappearance of deformity.

Comparison of the two arms showed that the deformity had only changed in character and not disappeared, for the humerus of the injured side seemed now abnormally short in comparison with that of the other. I availed myself of the new conditions to secure better motion to the elbow-joint, and to so apply lateral angular splints as to permit the epiphysis to remain in its new position on the shaft.

No inflammation or bad symptoms of any kind interfered with the healing process. At the beginning of the second week in February, 1878, the patient left the hospital convalescent. Last month, nearly two years after the operation, I had occasion to examine the arm again, and found it in a most gratifying condition. The humerus was a little shorter than that of the opposite side. Flexion was nearly perfect, but extension could be made only to an angle of about 115°.

As the free flexion permitted almost every use to which the hand could be put, and as the limited extension prevented only such uses as would require the arm absolutely straight, it can be readily seen that so far as usefulness was concerned, the patient had been vastly benefited by the operation.

As regards beauty, the present deformity would not attract the notice of any casual observer, while the awkward position entailed by an elbow dislocation forces itself on the observation of all.

This case confirmed the truth of Erichsen's assertion that muscular contraction has nothing to do with the difficulty of reducing an old dislocation of the elbow.

Division of the triceps, although it made possible the utmost freedom of flexion, did not facilitate at all the reduction of the luxation.

This experience has made me doubt whether fracture of the olecranon after Crosby's method, actually permits reduction. Fracture of the olecranon would undoubtedly make possible the same free flexion as tricipital tenotomy. It would cause the disappearance of the principal deformity, viz.: the undue projection of the olecranon; but how it could in any way relieve any obstacles to reduction which tenotomy of the triceps had failed to overcome, I cannot understand.

Now, when we consider that the only positive test of the reduction or non-reduction of a posterior dislocation of the elbow consists in a careful comparison of the relations of the olecranon process to the condyles, it becomes evident that fracture of the olecranon destroys the only test by which we can establish the true position of the bones in relation to each other.

As fracture of the olecranon has given to such patients more useful extremities, as it has enabled them to flex the forearm upon the arm, it has, of right, a claim to be considered a proper procedure.

It may not, however, be regarded as a mode of reducing the dislocation, and of bringing the joint surfaces into their old normal relations until exact post-mortem observations shall have shown such to have been actually the case.

It is unfortunate that we do not, as yet, understand the actual pathology of an ancient elbow dislocation. It is evident to me that muscular contraction plays little or no part in opposing the reduction. It is inconceivable that the mere interlocking of the bones should make so strong an obstacle. I can believe only that the ligamentous structures which are ruptured at the time of injury become glued so firmly to the bones as to prevent their disentanglement.

When we consider the extreme loss of function caused by such a condition, it does not seem to me good surgery to dismiss such cases unrelieved.

Our surgical resources for the relief of a chronic dislocation of the elbow are first, attempts at reduction by manipulation and extension. These rarely succeed after the lapse of three or four weeks. Second, fracture of the olecranon. This procedure relieves the deformity, and by permitting free flexion adds immensely to the usefulness of the extremity. I have already stated the reasons for doubting whether it ever facilitates the actual reduction of the luxation. I feel especially justified in adopting this view when on reading Hamilton's record of cases, I find two of said cases in which he expressly states that, though certain of having reduced the ulna by fracture of the olecranon process, he had been unable to bring the radius into place. It may be a fair question to ask, how he could be certain that the ulna was in place after its relations with the condyles had been destroyed by fracture?

The third method of treating an ancient dislocation of the ulna is that which accident demonstrated to be of service in the case I have just related. This could occur, of course, only in young persons, before the union of the epiphysis with the shaft. It occurred in my case as I was flexing, and at the same time pulling with considerable force on the forearm. Had the tricipital tendon not been previously divided, it is probable that the olecranon process would have broken instead, and that I should to-day have labored under the delusion that I had thus actually reduced the luxation.

Extreme flexion of the forearm, in children suffering from an ancient dislocation of the elbow, will be liable to produce either a fracture of the olecranon or one of the humeral epiphysis. Either occurrence would vastly improve the condition of the joint. Subcutaneous incision of the ligamentous structures around the joint has not been followed, so far as I know, by any benefit. The lack of positive knowledge as regards the nature of the obstacles to reduction make the procedure too blind to be of service.

There still remains two possible means of improving an old dislocation of the elbow. Excision of the joint has all the dangers and all the possibilities of that operation when undertaken for other maladies. I do not care, in this connection, to dwell upon it.

The other remaining operation is one that suggests itself to me as feasible and as offering hopes of better results than nature could ever possibly accomplish in a neglected dislocation. I hold in reserve as a procedure, which I shall not hesitate to resort to if I ever get the opportunity in a suitable case, the incision of the joints under the antiseptic spray; the division of all ligamentous and muscular obstacles which prevent reduction; the replacement of the joint surfaces, and subsequent strict attention to all the details of the antiseptic treatment. The elbow should, of course, in such cases be put in rectangular splints. Healing, if it occurred without suppuration, might reasonably be expected to result in a good joint, with tolerably free motion. If suppuration should take place, the anchylosed arm would be infinitely more useful in a flexed position than when nearly extended.

ANATOMY AND PHYSIOLOGY OF THE CHORDA TYMPANI NERVE.

By HORATIO R. BIGELOW, M.D.,

WASHINGTON, D. C

In an article upon the chorda tympani nerve, published in the *Archives of Medicine* for June, I expressed the opinion, which I had formed after numerous careful dissections, that this nerve was not united to the lingual "fibril to fibril," as Professor Sappey had claimed it to be, but that it was inclosed with it in a common sheath, receiving its special sensory functions from the ganglion, upon the nerve of Wrisberg. Continued investigation of its anatomy and physiology have not only strengthened this view, but have led me to other conclusions which may properly supplement my previous communication.

The intermediary nerve of Wrisberg and the main trunk are so intimately associated, before the chorda tympani is given off, that their differentiation is attended with the utmost difficulty, so that it is impossible to assert with certainty from which branch the filaments of the chorda tympani are derived. The fibres of each may be separated in their integrity for some distance; up to the very point almost where the chorda tympani is given off, the facial and intermediary nerves continue as separate and distinct. Both from its dissection, as well as from a patient observation of its physiology, I am quite persuaded that the filaments of the chorda tympani are furnished entirely by the intermediary nerve. The experiments of Vulpian and Prevost, of Bernard and Moss, all confirm this view. The ultimate anatomy can only be traced by the use of reagents, and of a good lens mounted upon a tripod, the fibrils being "teased" out with a needle. In this way the nerve of Wrisberg may be traced up as an entity, though closely connected with the main trunk, and arising from it the filaments may be seen which unite to form the chorda tympani. In the same way we may trace into the *intumescentia gangliformis*, by using a power of 1,000 diam., the nerve fibrils of the intermediary nerve, in the processes of the ganglion, at their junction with the cell, and these may be traced into the granular protoplasm. So also, the chorda tympani may be separated from the lingual and followed up. The terminal filaments expanding into the taste-cells of the beakers, the bulbous expansion at the end being identical with the transparent nuclei. The lingual has nothing to do with gustation, only in so far as it is influenced by branches from the chorda tympani. Experiments made upon dogs, trained in the manner described by Bernard, for noting the impairment of taste, have led me to the following conclusions:

1. The chorda tympani nerve is distinct and integral throughout its entire length.

2. It is derived from the nerve of Wrisberg, and not from the facial.

3. Its especial sensory function is derived from the ganglion upon the nerve of Wrisberg, into the granular protoplasm of which the ultimate fibrils may be traced.

4. The lingual branch of the fifth presides over general sensibility only. Isolation of the chorda tympani as completely as possible destroys the sense of taste in the anterior two-thirds of the tongue, the fibres undergoing degeneration.

5. Section of the lingual destroys sensibility, but only modifies the sense of taste, this modification being due exclusively to the branches from the chorda tympani.

6. Section of the facial, behind the origin of the chorda tympani, destroys the sense of taste—*very little of it*, and this, not because the facial at this point contains gustatory filaments, but because the nerve is cut off suddenly from its supply, and has received such a shock that it undergoes degeneration. If the chorda tympani be drawn out at the point where we first notice its filaments of origin, and divided, the sense of taste will be almost entirely destroyed. If the nerve of Wrisberg be cut in the aqueduct behind the ganglion, the sense of taste is lost. From which it may be inferred that the intermediary nerve is continued in the chorda tympani, and that this latter is a carrier of the sense of taste from the cells in the intumescentia ganglioformis.

The difficulty of noting the impairment of taste in lower animals is extremely great, and one will fail often before arriving at satisfactory results. The shock following the section of any nerve within the cranial cavity necessarily modifies exact conclusions, and as Flint very justly observes ("Text-Book Human Physiology," p. 761), "We must remember the difficulty of such observations, and we are to rely mainly upon the unmistakable phenomena noted in cases of affection of the chorda tympani in the human subject." Paralysis of the facial, behind the origin of the chorda tympani, is attended with loss of taste in the anterior two-thirds of the tongue. But this is not due, as I believe, to the existence of gustatory filaments in the facial itself, but to the fact that the transmitted shock is so great as to destroy the functions of the ganglion upon the nerve of Wrisberg, and in this way inhibit the special characteristic of the chorda tympani as a carrier of the sense of taste. The sensibility of the tongue remains, because it derives its sensory power from a different source; the cells furnishing the lingual branch of the fifth are not interfered with in such cases of paralysis. It is a fact, however, that sensibility is often modified, owing to the inability of the nerve-fibre, by reason of a degeneration, resultant upon shock, to carry the sensation. If we isolate, so far as it may be possible so to do, with a proper regard for the life of the animal, both the chorda tympani and intermediary nerves, the sense of taste becomes greatly modified, and after a time almost entirely lost, the feeble sensa remaining being due to the fibrils which it was impossible to divide. If there were essential gustatory filaments in the facial, the sense of taste would persist in a greater degree than it does after the division of these two nerves. If we are to study the functions of the chorda tympani from its action in those morbid conditions affecting it, the nature of the *shock*, as well as the resultant influence engendered by contiguity of structure, or by actual contact, must never be lost sight of. Nerves, themselves unmjured, may suffer in their action by transmitted influences.

MEDICINAL SPRING WATERS.—No. 2.

By JOHN C. PETERS, M.D.,

SEE PAGE

In my first article I gave what I conceived to be a fair specimen of the ordinary way of thinking and writing about medicinal spring waters. The first point which will strike the reader is that all these famous waters are composed of very common and well-known, and exceedingly cheap, medicinal ingredients. First we have *water*, more or less pure; next, *carbonic acid gas*; third, *table salt*; fourth, *carbonate of soda*; fifth, *sulphate of soda*; sixth, *sulphate of magnesia*, or Epsom salts; seventh, *carbonate of magnesia*; eighth, *carbonate of lime*; ninth, *carbonate of magnesia*; tenth, *iron*; eleventh, *muriate of lime*; twelfth, *muriate of magnesia*, while the traces of *bromide of magnesium* (¼ grain), and the still smaller relics of *iodide of magnesium*, which are found in the so-called iodo-bromated waters of Kreuznach, and the atom of *chloride of thorium* in the Baden-Baden waters, to which such wonderful effects are attributed, border closely upon the ridiculous.

There is a glamour about mineral waters which is excusable, perhaps, among lay persons, but should not be encouraged by such eminent authorities as once was Virchow, who, however, now is perhaps as much a politician as a scientist. It does seem a prostitution of his great scientific name to find it attached to high-sounding certificates for waters like Seltzer, Soden, Giesshübler, Ems, Vichy, Apollinaris, etc., all of which are composed almost exclusively of water, carbonic acid gas, and varying quantities of common bicarbonate of soda. Carbonic-acid water, with a little extra soda, according to the taste of the individual, and in some instances with a due regard for his personal or constitutional requirements, includes the whole of the magic of these waters, except the changes of air, scene, habits, etc., which are involved when the waters are drunk at the fountain-head or source. Fashionable people and gourmands, or simple thirsty souls, may profitably, perhaps, discuss the various merits or pleasantnesses of these waters, for there are smaller and more objectionable topics which are frequently debated about by these and other less agreeable people; but the medical profession should place them upon their true basis, that of more or less pleasant, refreshing, and even useful table and slightly medicinal waters, but which do not greatly excel in their virtues common, but good carbonic-acid water, or carbonated soda-water. There is not the slightest doubt that all these waters are serviceable, not only to wine-bibbers and gluttons, but also for some very estimable people who are troubled with acidity, or biliousness, or chronic rheumatism, or gout, obesity, the slighter forms of gravel and renal disease, some catarrhal and feverish affections, and even various thickenings of various tissues, caseous and firmer deposits.

If simple justice were done by Virchow and others to all these pleasant and even delicious *soda-waters*, there would not be much to complain of. But to stand out as the enthusiastic champion of one, to the exclusion of the rest, is manifestly unfair, unscientific, and unprofessional. It is doubtful whether true Seltzer water, viz: that imported in stone jugs, has ever been absolutely rivalled or excelled by any other natural soda-water; and it is equally true that artificial Bright'n seltzer still holds its own as almost unequalled in its class. But Giesshübler and Apollinaris are so good and palatable, that they may

justly be classed with the old favorites of table-critics; and Saratoga seltzer should not be forgotten. It is a mere matter of taste, and perhaps mainly of prejudice, when the artificial carbonated and soda-waters of Schultz, Hanbury Smith, Warker, and others, are slighted. All these artificial waters are made of good filtered and very pure water, and excellent soda and carbonic-acid gas; well prepared according to fixed formulæ, and have all the advantages of undeviating prescriptions, always composed of the same chemically pure materials, in well-established proportions and quantities. Medically, the differences between them all scarcely exceed that which is said to exist between *tweedle-dum* and *tweedle-dee*, except that we do not like Tweedism in anything. As a mere matter of taste or opinion—and the highest taste and the most scientific opinion always has respect for the merits of all other rivals—the preference for one over the other of these natural or artificial preparations is a matter solely of individual right or judgment. But some insist upon their rights too arbitrarily, and value their opinions too highly, and give them too strongly for the common comfort or welfare; and thus great injury is done to the interests, peace of mind, and opinions of others. This is to be deprecated, especially in so highly an honorable body as the medical profession, which should be above all ordinary partisanship. Great injury is done to the public at large by these exclusive and enthusiastic preferences, especially when strengthened by certificates which are circulated in newspapers, medical journals, circulars, labels on bottles, etc., etc. The dignity of the medical profession is not heightened in the estimation of the public when it sees Virchow's once immaculate name on soda-water bottles, or bottles of solutions of common purgative salts, and mixtures of Epsom or Glauber salts, in carbonic-acid water.

(To be continued.)

SOME THOUGHTS

ON THE IMPORTANCE AND EFFICACY OF

TREATMENT BY INHALATION, AND MEDICATION AND SUSTENTATION BY THE SKIN.

By JAMES G. CLARK, M.D.,

WEST NEW BRIGHTON, STATEN ISLAND, N. Y.

I AM fully persuaded that a radical improvement in several respects will take place in the treatment of disease, and that those maladies heretofore so stubborn, and almost beyond the reach of remedies will, most of them, if not all, be brought much more within the control of remedial measures. These conclusions are not the result of mere theorizing, but are founded upon experience and large facilities for observation. I have been a practitioner of medicine for over thirty-five years, and for twenty-five years did as large a general practice as perhaps any man in the State. Attended several large hotels; for ten years the Home for Orphan Children of Seamen, and other public institutions. In these years have seen and treated a great amount and variety of disease, and am free to confess that I have often mourned (as doubtless every conscientious physician of extensive experience has) over the inefficiency of treatment in many cases, and that too after having been aided by the most skilful experts within my command. For the past few years have spent a good deal of time in visiting the medical men and hospitals of many of the capitals of Europe; and the more I see of the methods of managing disease, the more convinced am I of the room for improvement, and that better results should be reached.

The diseases afflicting the human family arise from various causes. Some from poisonous inhalations, many from congestions and inflammations. Some from the ingestion of deleterious substances, and some again from actual contact with disease, etc., etc. In all these there are more or less alteration and vitiation of the vital fluid and derangement of the circulation. Nature, in her efforts to relieve the system, endeavors to throw off the deleterious elements mostly by the skin. The skin, therefore, is one of the most important tissues of the body—perhaps the most important. Is more highly endowed with nerves and blood-vessels than any other, and, as more than half of all that goes into the body passes off by the skin, it will be seen at once that it is a most important, if not the most important, depurating and eliminating organ of the blood-organism. To keep the skin in a healthy condition and have it perform its functions physiologically is of the greatest importance. To assist it in eliminating the deleterious elements in disease should be the continuous effort of the physician.

To aid in accomplishing this, I have contrived an air-tight receptacle that will contain the patient, from the cervical region, in the recumbent position. To this is attached an air-pump, by which the desired quantity of air (as indicated by a gauge) may be pumped from within—the effect upon the surface of the patient being watched through two little glass windows, one opposite the chest, the other the lower part of the lower extremities. There is also an opening in the receptacle through which steam or medicated vapor may be introduced. The effect upon the body, when placed in this partial vacuum, will be readily understood by every one—viz., that the atmospheric pressure being removed to the desired extent, the blood rushes to the surface, the cutaneous capillaries become distended, and the surface glowing, internal congestions and inflammations are relieved; poisonous elements circulating in the deeper vessels, disturbing the nervous centres, and impairing the functions of the viscera, are brought to the periphery and thrown off by the pores of the skin, which have been previously opened by cleansing, refreshing, and purifying washes (which remove the epithelial débris), and then treated by appropriate medicinal preparations, which readily find their way into the capillaries and go bounding along with the circulation, neutralizing and rendering innocuous whatever is hurtful to the organism. The readiness with which absorption takes place through the skin is well shown by the following case, as also the efficacy of medication by the surface. Some fifteen years ago a babe, three months old, suffering from cholera infantum and attenuated to the last degree, was brought from the city to the Latourette House, Bergen Point, and came into my hands. Its intra-uterine life had been six and a half months. This was well attested. The little creature was ejecting everything given it; and what to do, at first, was a puzzle—but something must be done, for all the ladies in the house had fallen in love with the little handful of humanity, and if the whole world had contained but this one baby the mother could not have been more anxious for its recovery. So we enveloped it in nice, soft, juicy beefsteaks, renewing them as often as the heat

of the weather rendered necessary, preceding their application by a very delicate mechanical substance, giving to the mouth almost nothing, and thus we went on day by day.

The babe recovered, grew strong and well, and four years afterward became again my patient at Potter's Hotel (now St. Mark's), for a bad scald of the chest which she went through as bravely as if she'd been born at full term and had not had her life saved by lard-tasks externally applied. Another case forcibly illustrating the rapidity with which absorption takes place is given by Sir Te Hill: "A jockey had been for some time in training for a race, in which that gentleman was much interested, and had been reduced to the proper weight. On the morning of the trial, being much oppressed by thirst, he took one cup of tea; and shortly afterward his weight was found to have increased six pounds, so that he was incapacitated for riding. At least three-fourths of this increase was from cutaneous absorption, which function was suddenly stimulated by the cup of tea." I might give many other cases similar to that of the babes in my own practice, perhaps not quite so marked, but where the result was quite as favorable—fully demonstrating the efficacy and efficiency of peripheral medication and sustentation. Along with this form of treatment by the surface, goes admirably well the introduction of medicaments into the circulation by inhalation. This is a very easy and very powerful way of combating disease. As it is through the air passages that many pernicious elements enter the system, it would seem very natural that by the same ingress the correctives and antidotes should be sent; and all know how efficiently agents act given this way—as chloroform, nitrous-oxide gas, oxygen, etc.

In many diseases, as typhus and typhoid fever, and the typhoid stage of other diseases, the tongue and mucous membrane become hard, rough, and as dry as a chip. The lining of the stomach is mostly in the same condition (for the tongue is the mirror of the stomach), and medicines placed in it are of no avail, for there is no action, no absorption, and they lie there dead and inactive. Now, you might as well place a weasel in a tightly cemented room from which there is no point of exit, and expect it to rid the house of rats, as to expect medicines placed in the stomach under these circumstances to have any controlling or curative influence over disease; and yet this is just what is done over and over again, indeed all the time, by physicians of every school everywhere. Not so do medicines act when given by inhalation; for, carried to the delicate vesicular membrane in thorough solution, they quickly enter the circulation, and, unimpeded by any action of the gastric juice, commence their neutralizing and curative work at once, and if properly and judiciously administered in conjunction with the use of the vacuum receptacle, and proper applications to the surface, I am sure that many diseases that are now the opprobrium of the profession will be rendered much more amenable to treatment. Of course there are many affections that readily yield to treatment by the stomach. Indeed, I believe that one-half of all the ailments to which humanity is liable may be controlled by the "vis medicatrix naturæ" alone, and would get well without any treatment further than the proper regulation of diet and exercise. Then, again, there are some affections in which all remedies by the stomach are at times wholly inefficacious, even when that organ is in a good working condition. I remember a striking case of this sort in a young lady suffering from ovarian neuralgia, which came on regularly every morning, and was very severe. I used everything in the way of anti-periodics, anodynes, counter-irritants etc., that I thought applicable to the case, but with no apparent permanent good result. The father, tired of seeing his child suffering so, took her to a known homœopath in the city, and he encouraged them greatly by saying that the trouble was not ovarian, but in the kidneys, and that he'd make short work of it; but he was longer at the case than I was, and no more successful when the electro-chemical baths were instituted. The first one of which brought entire relief. I had at one of the hotels a case somewhat similar and severe case, in the management of which were associated with me three of the best physicians from the city, and in this case, too, medicine had only a very slight temporary effect. The cure was effected quickly and permanently on the tenth day by electricity. While I think this treatment applicable in most cases, it is more particularly so in those of internal congestions and inflammations, in eruptive and congestive fevers, and impaired circulation.

Take a case of double pneumonia in disease that for the past few years has been so fatal in New York City's, where the patient can hardly breathe from the pressure of the engorged blood-vessels upon the delicate air-vesicles and capillary bronchial tubes, and is being rapidly poisoned by the circulation of unaerated blood—can a more powerful method be conceived of for drawing away the blood and unloading these pulmonary vessels, than by placing the body in this vacuum receptacle and diverting the circulation to the surface, when the lung tissue, being relieved from pressure, an can be admitted, and medicaments and oxygen by inhalation? What, think you, are the chances for the patient thus relieved, as compared with his chances under the ordinary treatment?

The poison of scarlet fever is so deadly sometimes that it will destroy life in twenty-four or thirty-six hours. This I have seen more than once, and mourned over the helplessness of our art to save the beautiful child. Here, again, what could so powerfully and certainly bring the blood to the surface and expel the poison through the proper outlets?

Take paralysis dependent upon a clot in the brain, what process could so quickly and surely lessen the pressure and hasten the absorption of the clot as this?

Take typhus or typhoid fever, or the typhoid stage that any disease may run into, or the various forms of nervous affections so prevalent just now, dependent mostly upon engorgement about the nervous centres, causing cold hands and feet, and a morbid sensitiveness to low temperatures; or take chills and fever (the curse of so many localities), the essential conditions of the chill being a small, hard pulse, peripheral anæmia, and convulsive muscular contractions, caused by a congested condition of the deeper blood-vessels containing more or less malarial poison acting upon the nervous centres; and does not this treatment present itself as foremost and infinitely superior to the large deafening doses of quinine, or the new and lately more fashionable, but dangerous remedy, pilocarpin, which relaxes arterial tension, causes a determination of blood to the surface, and, by the diaphoresis induced by it, brings about muscular relaxation—all which the vacuum receptacle will do with more certainty and without danger. I might go on in this way for an indefinite time, but am persuaded that the simplicity, efficiency, and practicability of this form of treatment are apparent

to every one who will reflect for a moment, and must be admitted by all. I do conscientiously believe that by the inhalation of medicaments, carefully prepared and judiciously administered—by the application of medicaments, carefully prepared and properly applied, after the skin has been well cleansed (all dead epithelium being removed), together with the use of the receptacle, a new era in the treatment of disease will be inaugurated, and a success attained in the curing of the graver maladies that will surpass anything yet realized.

It has often occurred to me that the importance of atmospheric pressure, as affecting the health and general condition of mankind, is not sufficiently estimated. I believe with a celebrated writer, who said: "Give me the physical aspect of the country, and I'll give you the character of the inhabitants." And he might have added, the physical development also. All know that elevated situations for habitations are much healthier than those in the valley or low places. Some will say because the air is purer, and in this they are correct so far as they go; but it is well known that as we ascend, the atmospheric pressure lessens, and if we go high enough this will be unpleasantly demonstrated by blood issuing from parts of the body. When a suitable elevation is reached, the peripheral circulation is much increased; the action of the lungs is freer and fuller, and a feeling of exhilaration is experienced from the improved oxygenation of the blood. Therefore, how infinitely better it would be for the health of the denizens of cities to pass their summers among the mountains, than at the crowded places of fashionable resort! What a marked improvement there would be, not only in their physical, but mental condition (to say nothing of morals), in the course of two or three years' living rationally, exercising judiciously in the fine, exhilarating mountain air! One of my patients who suffered much from asthma, spent a winter at the Fifth Avenue Hotel. After a little he discovered that he could live much more comfortably, with much less dyspnœa, on the fifth floor than any lower down—and here, of course, he fixed his quarters. With the lessening of the surface-pressure his peripheral capillary circulation was increased, and his lungs correspondingly relieved. How large a number of persons suffering from lung trouble have been greatly benefited by living in the Adirondacks! One occasionally being obliged to remain there throughout the winter, as was the case with a physician of some note, who, while remaining in those mountains, enjoyed fair health; but each time, on coming to the city and remaining a short time, would have hemorrhages, night-sweats, and all the symptoms of rapid tuberculosis, rendering his flight to the mountains, and remaining there, imperative. Doubtless the importance and benefit of keeping the skin of animals in good condition is patent to all, for no animal will thrive and do well unless this be the case.

For many years I have been a strong advocate for the clipping of horses, and invariably have it done every winter on every horse whose hair is too long and thick to admit freely of the brush and curry-comb reaching the skin. Some years ago I had a horse who threw out early in the fall a very thick, heavy coat. Soon the legs began to swell, which increased daily, notwithstanding the giving of purgatives, diuretics, and free rubbing, all which were resorted to, as I did not want to clip so early; but all of no avail. The horse was clipped. A greasy scum all over his skin (which the comb and brush could not reach) was removed by a wash of whiskey, water, and borax; and *now*, after a drive, all swelling was gone and did not return—and in eating, driving, and feeding he was a new horse.

Clipping the horse when the hair is coarse, thick, and long, is the very best thing that can be done, for he will do a third more work on a third less feed, and is a merciful and not a cruel procedure. I also recommend the clipping of cattle that are being fatted, where the hair is long and coarse, believing—indeed, knowing—that such cattle would fatten much easier, and the meat would be more tender and much sweeter.

In a word, I have long been impressed with the belief that not a tithe of the attention to the condition of the skin in disease, and what may be effected by medication and sustentation thereby, is given by physicians, and until this is done, the success that should be attained will not be reached.

True, Europe has its mud-baths, and Philadelphia its mud-poultices; and we have Turkish baths and Russian baths, and all kinds of baths, and all are good as far as they go; but, to our mind, repeated daily thorough cleansing of the skin by medicated washes, and the insuring a free peripheral capillary circulation, are the prime essentials in the treatment of disease.

MULTILOCULAR OVARIAN CYSTS; SEMI-SOLID CONTENTS; OVARIOTOMY; RECOVERY.

By G. E. BENSON, M.D.,

HUDSON, N. Y.

Mrs. M——, aged forty-three; healthy-looking, and robust; the mother of eight children, the youngest two and a half years old, living in a part of the city where sanitary laws and regulations are little observed, was seen by me in March last, for relief of dysuria. The catheter was passed, and appropriate remedies advised, with some relief to the symptoms. When seen again, in August, the vesical irritation was not complained of, but the abdomen was greatly enlarged, though not uniformly so. In the right groin, from a little above Poupart's ligament to a line on a level with the umbilicus, was a globular mass, firm, but fluctuating; easily defined and perceptible in outline to the eye when the patient lay upon her back; in the left side was a similar, but larger mass, not so low down, but extending upward almost to the false ribs; and between these masses was a distinct depression in the median line, giving the appearance of two distinct tumors. The uterine sound was passed nearly three inches, and a little to the left, and easily movable. The menses appeared every three weeks, but usually in less than normal quantity. The hypodermic needle was plunged into both masses, and a straw-colored fluid obtained, which differed so much in appearance as to lead to the belief that the cysts were separated by partition walls, or that both ovaries were diseased. A distinct wave was communicated, by striking one side, to the hand placed over the other.

On October 1st I was sent for in haste and found the patient suffering from severe pain in the abdomen, which was now very much distended and tender upon pressure; skin hot; pulse 120; temperature 103°; respirations 24. A hypodermic injection of ¼ grain of sulph. morphia was given; turpentine fomentation applied; and by the aspirator about two pints of fluid withdrawn, with relief to the symptoms

in a few hours. From this time upon the use of quinine, tincture of iron, and an occasional anodyne, she improved up to the day of operation, although she was not able to sit up. The pulse remained near 100; the appetite was poor. Slept little, unable to lie well down from the distention.

On October 6th, after consultation and with the hope that the patient would not at any future time be in a better condition, if as well, it was determined to attempt to give her relief by an operation. At this time the pulse was 102, not full; temperature 101½; tongue slightly coated; had slept fairly during the night from the effects of an anodyne; had two motions yesterday.

When under the effects of ether, an incision was made from just below the umbilicus to near the pubes in the median line. The cellular and adipose tissues were engorged with blood; and the peritoneum, when reached and lightly opened, gave out to a large quantity not measured of clear straw-colored fluid. The incision was completed, the tumor came in view, was pierced with a trocar, and near two quarts of fluid evacuated. By directing the canula in different directions it was ascertained that the remaining contents were semi-solid. Several bands of adhesion of a recent date, were in front and to the left side, which were easily separated; but while passing the hand around to the right side, the cyst-wall burst, and let out a considerable quantity of purulent-looking fluid, which was to a great degree evacuated externally by inclining the patient to the side and pressing together the sides of the wound. Very firm and old adhesions extended to the right side of the pelvic cavity, which were with difficulty broken by the fingers, and without any subsequent hemorrhage. The incision was extended two inches above the umbilicus, the tumor (weighing twenty-five pounds) turned out; the pedicle, found to be of fair length, was transfixed with a carbolized strong silk ligature, tied and separated.

The intestines were mahogany color, very vascular, appearing like mucous surfaces. The peritoneum was mottled with reddish patches of adventitious membrane and very vascular, scarcely retaining any resemblance to healthy serous membrane. The fluid remaining was absorbed by balls of carbolized lint, the wound closed with silver wire sutures, including the peritoneum, the pedicle brought out at the lower angle and retained by transfixing with a pin, aided by silver sutures in upper and lower border passing through the edges of the incision; a drainage-tube passed down into the pelvic cavity, the usual dressings applied, and the patient was carried to her bed.

For forty-eight hours no notes were kept. The pulse was fast, feeble, and irregular; temperature but little raised; slept little; took iced milk freely, but could not retain brandy. Rectal injections not retained.

October 8th.—Reaction occurred this morning. Sleeps more quietly, and during the day four or five hours. 10 P.M.: Pulse 96 to 108, firm and of fair volume; temperature 102½, respirations 18; urine, twelve ounces in twenty-four hours; skin warm and dry; tongue slightly coated and moist; stomach retains plenty of iced milk and cream, but will tolerate neither brandy nor quinine. The bowels are quiet, have not moved since the 7th at noon; mind clear. Ordered three grains of sulphate of quinine, one ounce of brandy and one ounce of cream as an enema; to be followed by a two-grain opium suppository. Repeat enema in six hours.

October 9th, 9 A.M.—Pulse 108; temperature 102½; skin moist, abdomen more distended than yesterday, three motions of bowels last night, slept two or three hours, mind clear, no vomiting. The injection was not repeated. A suppository was given at 4 A.M. and again at 9. Continue iced milk, and give brandy in teaspoonful doses. 9 P.M.: Pulse 104 to 108, respirations 20, slept half of the day; bowels moved once; four ounces of urine drawn—not albuminous. Takes plenty of milk. Ordered half an ounce of brandy every hour and a suppository every four or six hours, as required.

October 10th, 9 A.M.—Slept the most of the night; had two movements of bowels, mostly flatus, which relieved the tympanitic distention; pulse 102 to 108; temperature 101½; skin moist, wound dressed and looks well, mostly united; drainage-tube has slipped out; a serous fluid drains away from the lower angle of wound; mind clear, has taken two ounces of brandy during the night. 9 P.M.: Pulse 100 to 104; vomits during the day from heat of atmosphere; bowels have not moved to-day; sleeps the most of the time; temperature 99°; draw off eight ounces of urine. Ordered half a goblet of iced milk and half an ounce of brandy every hour. Suppository at usual intervals.

October 11th, 9 A.M.—Slept well during the night; pulse 96, regular; temperature 99; tongue moist; tympanites much less, discharge very free at lower angle of the wound; slight motion of the bowels this morning of more consistence. 9 P.M.: Pulse 102; temperature 101°; tongue moist; bowels moved once; sleeps half of the time. Continue treatment.

October 12th, 9 A.M.—Passed a restless night; pulse 130, soft, and a little irregular; temperature 97; one motion, considerable discharge from abdomen; increase the quantity of brandy, otherwise continue. 9 P.M.: Pulse 140; respirations 28; temperature 100; sleeps well; two motions, which are yellow and consistent; tongue moist; slight coldness of extremities. Has taken to-day one quart of milk and eight ounces of brandy. Ordered two grains of quinine every two hours.

October 13th.—During to-day the average pulse is 140, not steady; temperature normal; two motions; no vomiting; morale good. Increase the brandy to a pint in twenty-four hours, also give fifteen drops of tincture of muriate of iron every two hours. Quinine agrees well. Large discharge of pus from lower angle and from one side of the pedicle.

October 14th, 9 A.M.—Pulse 140, a little firmer; temperature 99½; sleeps well; takes a pint of brandy a day without inconvenience; bowels quiet; tolerates iron well; less discharge of pus from abdomen; coughs some. 9 P.M.: Pulse 130; temperature 98; one motion; had one suppository to-day. Ordered one raw egg in milk every four hours. Other treatment the same.

October 15th.—During the whole of this day the general condition has changed but little. Pulse average is 130, more regular and firm; had one suppository in early morning; respirations 24; temperature normal. Takes, in twenty-four hours, a pint of brandy, six eggs, two and a half quarts of milk, fifteen drops of iron every four hours, and two grains of quinine every two hours.

October 17th.—Since last report the pulse has improved in volume, but remains 130 to 140; temperature nearly normal, though last evening it was 102—now (9 A.M.) 100½; respirations 24; bowels confined; urine free. Takes the same quantity of brandy, milk, eggs and iron, and this afternoon a little

hashed rare beefsteak. Both ligatures from pedicle came off to-day. Some drainage of pus from abdomen. Patient cheerful.

October 18th.—Passed a good night. Pulse 120, and better; temperature normal; wound discharge purulent; small slough of cellular tissue at site of pedicle; bowels quiet. No change of treatment.

October 19th, 9 P.M.—There is little change. Pulse 120 to 130; temperature normal; ate to-day chicken with broth; continue six eggs a day and half the quantity of brandy. Quinine continued.

October 20th, 9 A.M.—Had a good night. Pulse 108 to 112, and firmer; temperature normal; tongue clean; no motion of bowels in forty-eight hours. Ordered warm-water enema. Continue treatment. Is improving.

October 21st.—Pulse 96 to 108; sleeps well; tongue clean. Breakfast was toast and cup of coffee. Takes less brandy. Continue milk and eggs.

October 22d.—Pulse 78, and regular. Ordered quinine and iron every three hours. Continue eggs and milk, and diminish the brandy.

October 24th.—Pulse 76; appetite good; bowels soluble by the aid of enemas.

The improvement has been uninterrupted to the date of this report of the case (November 18th). The site of the pedicle is not entirely healed, and there is a slight purulent discharge from beneath, but probably not from the peritoneal cavity. Success has been owing, no doubt, to the free drainage, and to the ability to retain, with no vomiting, a large quantity of stimulus and nutritious food. Neither peritonitis nor septicæmia, to any great degree, seemed to attend the progress of the case.

Progress of Medical Science.

On the Effects of Tayuya in Syphilis.—Prof. Geber, of Klausenburg, reports in extenso with the histories of cases, the results of an extended trial of the tincture of tayuya in venereal diseases. He employed it in forty-seven cases, which included cases of soft and indurated chancres, and of macular, papular, pustular, and ulcerated syphilides. He administered it internally and by subcutaneous injection, using doses in some cases much greater than those usually recommended; he also employed it externally as a wash. The results of his experiments may be summed up as follows: Tayuya checked pretty rapidly the progress of soft chancres, and caused even gangrenous sores to improve in a relatively short time, but complete recovery took place very slowly under its influence. In hard chancres it was useless, as it hastened very little, if at all, the progress of cicatrization, and had absolutely no effect on the induration. When administered internally in cases of constitutional syphilis, the results were so far negative that it remained a question whether, in the few cases in which the eruptions disappeared under its use, the improvement was really due to the tincture of tayuya. In no case could its effects be regarded as at all comparable to those of iodide of potassium or of mercury administered internally. When employed subcutaneously it effected a complete cure in a few cases, and produced improvement in others; in the more severe cases, however, it either proved entirely useless, or the slight improvement secured was obtained at such an outlay of time and pain, that the method of treatment could not be compared with the subcutaneous injection of corrosive sublimate or with the inunction cure.

In cases of ulcerated papules, tayuya, employed locally, produced cicatrization rapidly, but had absolutely no effect in hastening the resorption of the infiltration. The most valuable effects were observed in cases of papular syphilides of the mouth, which disappeared with satisfactory rapidity when painted with tayuya. Here, however, it must be assumed to have acted less as a specific against syphilis than as a styptic, since equally good effects can be obtained with solutions of nitrate of silver, tannin, etc. Prof. Geber concludes with the expression of his conviction that the tincture of tayuya is not destined to usurp the place of either of the old antisyphilitic remedies, to which it will always hold a very inferior position.—*Vierteljahresschrift f. Dermat. u. Syph.*, 1879, 2 and 3 Heft.

A Case of Cysticercus Cellulosæ Cutaneus.—Dr. Schiff, of Vienna, reports a case of multiple subcutaneous tumors in which the diagnosis of cysticercus cellulosæ cutaneus was made and verified by microscopical examination. The affection seems to be a rare one in Vienna, or, at all events, it has scarcely ever been recognized there during life, although Rokitansky had met with it several times in the dissecting-room. Dr. Schiff's patient presented a large number of tumors scattered all over the body, and varying in size from a pea to a hazelnut. The tumors were situated under the skin in the subcutaneous connective tissue, and were only loosely attached to the skin and the subjacent structures, as was evident from their mobility. Their consistence was rather difficult to define, as they felt hard like cartilage, and at the same time possessed a certain elasticity. Their surface was invariably smooth. The patient, an intelligent young man, stated that he had noticed the first tumor a year previously, and that subsequently the others had made their appearance at short intervals. About the time the first tumor appeared, the patient had an epileptiform attack, which was repeated several times during the year. He also suffered frequently from attacks of nausea, and pains throughout the entire body. These symptoms were thought by Dr. Schiff to be due to the presence of cysticerci in the brain. The patient was also subject to a peculiarly severe muscular tremor of the entire body, but particularly of the arms, which had first appeared at the age of ten years, after an attack of typhoid.—*Vierteljahresschrift. für Dermat. u. Syph*, 1879, 2 and 3 Heft.

Cholelithiasis as a Cause of Cirrhosis Hepatis.—Cases of cirrhosis due to cholelithiasis have been recorded by several observers, but they are still so rare that the following case from the practice of Dr. Roller, of Trier, possesses considerable interest: A woman, 69 years of age, who had never been addicted to drink, died after suffering for some months from the usual symptoms of cirrhosis of the liver. The autopsy showed general peritonitis of old standing, with signs of a recent inflammatory exacerbation; a perfect anatomical picture of interstitial hepatitis; a gall-bladder presenting the residue of old inflammation, and containing a large gall-stone. As in this case alcoholism could be absolutely excluded, the gall-stone was regarded as the primary cause of the hepatic disease. The various steps of the morbid process were thought to be as follows: First, the gall-stone excited an inflammation of the gall-bladder which resulted in thickening of its walls. From this starting-point the inflammation extended in all direc-

tions, but particularly to the tarry evacuations, as was evidenced by the blackness of the adhesions which bound the right thorax to the gall-bladder. The inflammation except into the liver along the pathway furnished by the serous capsule, here it led to the development of new connective tissue and the resulting cirrhosis.—*Berliner Klin. Wochen.*, No. 42, 1879.

NITRITE OF AMYL IN ACUTE.—Dr. W. E. Saunders, of Lahore, recommends the use of nitrite of amyl to cut short the paroxysms of fever. He has found that the amyl removes the attack in about one-third the usual time, and, in most cases, the fever does not return. He mixes the nitrite with equal parts of oil of coriander, to render it less volatile and to cover its odor, and administers four drops of the mixture on a small piece of lint, permitting the inhalation to continue until flushing of the surface and a sensation of warmth is perceived. Profuse perspiration sets in within a few minutes, and the attack speedily ends. When administered in the cold stage, both the hot and sweating stages are sometimes avoided.—*The Buffalo Medical and Surgical Journal*, December, 1879.

PERITYPHLITIC ABSCESS ASPIRATED THROUGH THE RECTUM.—A very interesting case of perityphlitic abscess, successfully treated by aspiration through the rectum, is reported by Dr. L. D. Merriam, of Conneaut, Ohio. After running a favorable course, fluctuation was discovered on the twelfth day at the right side of the rectum, about two and a half inches from the anus. On the fourteenth day the abscess was punctured with the largest needle of Dieulafoy's aspirator, and one pint and three-quarters of fetid pus drawn off. No pus was formed after the operation, and the patient was discharged cured two weeks later.—*Buffalo Medical and Surgical Journal*, December, 1879.

BALSAM OF PERU IN PRURITUS.—In a communication to the *Deutsche Med. Wochen.*, No. 34, Dr. Auerbach, of Berlin, states that having, in common with so many other practitioners, found the balsam of Peru a most valuable remedy in itch, he has for some time past used it in the treatment of pruritus, with the greatest success. After the first rubbing into the part affected, great relief is obtained, and in a few days a cure results. He relates a very obstinate case, which, after resisting all kinds of treatment for years, was speedily cured by the balsam.—*The Medical News and Library*, December, 1879.

A CASE OF "RECURRING FIBROID."—An interesting case of a myxo-sarcoma of the back, upon which twelve operations were performed in thirty-nine years, is reported by Dr. Green, of Elizabeth, N. J. It is probable that the growth first developed from the soft tissues of the back, but after the second operation the recurrence of the tumor was always accompanied by partial paralysis of the lower extremities, and at each successive attempt at removal it was found necessary to advance further and further into the space between the second and third dorsal vertebræ, in which direction the neoplasm was constantly extending. Each operation succeeded in relieving the paralytic symptoms, either partially or completely, with the exception of the last, which was performed two months before death took place, and from which no relief was experienced. At the autopsy the left pleural cavity was found filled with partially coagulated blood, which came from the posterior and upper portion of the lung, at which point the pulmonary substance was broken down from the pressure of the advancing tumor. The mass of the tumor was situated in the posterior mediastinum, and was at least seventeen inches in circumference and weighed about a pound and a half. It was pronounced by Drs. O. Heitzman and J. B. Hunter, of New York, to be a myxo-sarcoma. The large mass in the thorax was continuous with a smaller one passing through between the second and third ribs of the left side to the corresponding intervertebral foramen, and through this to the interior of the spinal canal, in which situation the growth was about the size of a small cherry, and was loosely attached to the dura mater. The meninges at the point were thickened and opaque. The second and third dorsal vertebræ were roughened and partly absorbed near the intervertebral foramen, by the pressure of the tumor.

NITRITE OF AMYL IN UTERINE HEMORRHAGE.—For some years Dr. Koechlin has, with great benefit, made use of warm fomentations to the head in cases of uterine hemorrhage, the object of these applications being to prevent anæmia of the brain, and of the heart. Convinced of the success of this mode of treatment, and supposing the result to be due to the rapid dilatation of the cerebral vessels, Mr. Kerr argued that in nitrite of amyl we had a more rapidly acting and more powerful agent to produce a similar effect. This idea occurred to him when attending a case of rather severe *post-partum* hemorrhage; and, happening to have some of the drug with him, he at once put his theory into practice by administering five minims, by means of a Skinner's inhaler, with immediate and most satisfactory results. The hemorrhage ceased at once, and permanently, and the patient was restored from a state of collapse. Indeed, in this latter respect, its effect was only comparable to that of the hypodermic injection of ether. Mr. Kerr has not been able to find any notice of nitrite of amyl having been heretofore used with the above views, and, of course, a single case would hardly suffice for a general inference, but he promises to give the medicine a more extended trial.—*The British Medical Journal*, November 1, 1879.

THE TREATMENT OF MUCOUS POLYPUS OF THE NOSE.—In some cases of polypus of the nose, Mr. Reginald Harrison, F.R.C.S., has recently been adopting the following treatment, which has given good results. In structure, these growths consist of little more than connective tissue infiltrated with serum, and enclosed with something resembling mucous membrane; when removed by avulsion and exposed to the atmosphere, they rapidly shrivel by the escape of their serum; their distended grape-like appearance being exchanged in a short time for that represented by little more than a few shreds of connective tissue. The treatment adopted consisted in freely puncturing these growths from the anterior nares by means of an ordinary acupuncture-needle, thus allowing the fluid of which they largely consist to drain away. To prevent them from refilling, a solution of carbolic acid and glycerine, which has a most marked drying-up effect, is daily injected into the nostrils for some time. In this way many cases were dealt with successfully where the growths were of a limited nature and the patient averse to their avulsion.—*The British Medical Journal*, November 15, 1879.

THE TREATMENT OF PORT-WINE MARK.—Vertical linear scarification, first proposed by Mr. Balmanno Squire as a remedy for port-wine mark, has in many instances been found less efficient than was hoped,

owing to the fact that the operation did not effectually cut off the supply of blood derived from the tissues immediately beneath the mark. To effect this object, Mr. Squire proposes to use oblique instead of vertical incisions, by which means the blood-supply to the over-vascular skin may be cut off in all directions, except through those limited channels which subsequently become re-established. Two operations are necessary. At the first, after freezing the skin with the ether-spray, the affected part is cut with a scalpel into a series of minute squares; but the instrument, instead of entering the skin perpendicularly, enters it obliquely—that is to say, at an angle of 45 deg. with the surface, so as to divide the skin, not into a series of vertical slices, but into a series of slanting flaps. The second operation is precisely the same as the first, only the slants are precisely the opposite of those used on the first occasion. Bleeding is almost absolutely prevented by exercising effective pressure on the surface operated upon for about ten minutes continuously.

Mr. Squire is now engaged in devising the construction of an instrument with many blades, for the prompt performance of this operation. It is an instrument similar in many respects to his (vertical) multiple linear scarifier, which, perhaps, explains itself sufficiently by its name.—*The Medical Press and Circular*, Nov. 26, 1879.

Unusual Development of Keloid in Small-pox Scars.—Dr. Goodhart presented to the Clinical Society of London an interesting case of keloid which developed in the scars left by an attack of small-pox. The patient was sixteen and a half years of age. He was in bed four months, and during that time the present disease came on. Since then it has been slowly decreasing. The face and neck, shoulders and upper extremities, and legs are the parts most affected. On the thighs it attacked the seat of old bed-sores, and over each great trochanter and over the sacrum there is a similar keloid scar. The appearances vary somewhat in different parts. The case was presented to the Society, first, because it seemed to be a very unusual extent of development of keloid, and in reference to its etiology it seemed possible that in the cicatrices of small-pox there may be some unusual facility afforded to such a growth as this, since keloid has been observed to take place not unfrequently in vaccination scars; secondly, to hear from any member who may have seen a similar case, whether it is justifiable to hold out to the patient a hope of ultimate cure; and thirdly, it was desired to show the case at an early stage, that, if anything unusual happened, he might be exhibited again at some future time.

In the discussion which followed, but little light was thrown on the question of prognosis. Mr. Heath considered the case to resemble in character the ordinary keloid, but unlike the variety known as Addison's. He had not known a keloid developed after a burn to disappear. Mr. Gant drew attention to the fact that one of the most interesting features of the case is the marked symmetry of the growth. He thought the development of the keloid might be intimately dependent on the condition of the blood, and he further showed how the influence thus exerted can be traced in numerous instances. Mr. Golding Bird detailed a case of which he was himself the subject, in which keloid succeeded to a boil, and, continuing to grow for a year, was raised as much as one-third of an inch from the shoulder, and as large as a split hazel-nut. At the present time, three years after, the skin presents only a white scar.—*The Medical Press and Circular*, Nov. 19, 1879.

Enlargement of the Bronchial Glands in Whooping-cough.—Dr. Noël Guéneau de Mussy considers the peculiar character of the cough, and the spasmodic symptoms of pertussis, to be due to the pressure of enlarged bronchial lymphatic glands upon the vagus. The following are the reasons upon which he founds his theory:

1. There is a close resemblance between the fits of cough in some cases of bronchial adenopathy and the fits of whooping-cough.

2. The persistence of whooping-cough during months and years is easily to be understood if this spasmodic cough be consecutive to the enlargement of the bronchial glands; but it would be difficult to explain if it is to be considered as the continuation of the primary disease. Whooping-cough has a great affinity with eruptive fevers, and consequently would be incompatible with chronicity. The enlargement of the lymphatic glands, on the other hand, may outline the irritation which produced it.

3. It is easy to explain by this theory the seemingly new attacks of whooping-cough which any irritation of the respiratory organs may excite after the disease has apparently subsided; a fresh congestion is added to that which has not thoroughly disappeared, or to a congestive disposition left by the whooping-cough in the glandular tissue.

4. The appearance of the characteristic cough only in the second, or even the third week of the disease, is easily to be understood, if it succeed an enlargement of the bronchial glands, which is evolved more or less slowly, and only produces irritating action on the inferior laryngeal, or other parts of the vagus nerve, when it has acquired a certain degree of development.

5. It is yet to be understood that this characteristic cough may be absent in the case of persons who, living in the midst of whooping-cough patients, and not having previously themselves been affected with that disease, present a cough which persists during several weeks—a sort of mitigated whooping-cough—when the glandular enlargement was little developed.

6. Vomiting may also be traced to the same morbid condition, and it is probably more frequently excited by adenopathy of the left than of the right side. This prevalence of vomiting in the enlargement of the left lymphatic glands may be explained by the greater share which the left pneumogastric nerve has in the innervation, and consequently in the motricity of the stomach.

7. The compression of the laryngeal nerve by enlarged glands explains the cases of aphonia, generally transitory, but which has been known to exist for four years in a case exhibiting all the signs of an enlargement of the left bronchial glands.—*The British Medical Journal*, Oct. 25, 1879.

Discussion on Antiseptic Surgery.—A very important debate on the subject of antiseptic surgery took place at the Metropolitan Counties' branch of the British Medical Association in London, Dec. 3d. It was opened by Mr. MacCormac, who spoke in defense of the Lister method. Mr. Bryant, Mr. Barwell, Spencer Wells, and T. Smith followed, and the discussion was closed by Prof. Lister himself. Mr. Bryant commended, but did not advocate the Lister method. The others spoke more or less favorably about it.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 17, 1880.

THE AMERICAN MEDICAL ASSOCIATION.

THE coming meeting of the American Medical Association, which is to be held in New York, has every promise of being a success. Already the committee of arrangements have had several meetings, suitable buildings have been secured, and the necessary steps have been taken to provide for social as well as scientific entertainments. In view of the large number of delegates who will probably attend, it is quite desirable that the work of the sections should be thoroughly systematized, so that every one who has anything to say should have the opportunity of saying it within a reasonable space of time. To such an end, the proper way would be for each delegate intending to read a paper to notify the Secretary of the Committee of Arrangements, at the same time sending an abstract of the same.

We have, time and time again, deprecated the practice of reading long papers before medical societies. It has been said of a successful clergyman, that he never expected to convert any one if his sermon extended beyond twenty minutes in length. If readers of medical papers could bear this in mind and apply it to their own case, it would be placing the listeners under lasting obligations. We do not mean to say that each author should not attempt to exhaust his subject and work it up in detail, but simply that such a paper, as a whole, should not be inflicted upon the sections. There never is time for such things. Every one is tired before the discussion commences. The proper way to meet the practical requirements of the meeting, is to read the papers in abstract, bringing out in the latter any points which may be necessary to invite discussion. Then every member has an opportunity for the expression of his particular views, at the same time every opportunity is offered for the presentation of a large number of papers. As a matter of course, the papers themselves can be published in full in the Transactions and read at leisure.

Another advantage in furnishing the communications in abstract is that the committee will thereby be able to furnish members with all the information necessary to prepare them for the intelligent discussion of the various subjects. This was done with excellent result at the recent meeting of the International Medical Congress at Philadelphia, and we do not see why the plan could not bear repetition during the coming meeting of the Association.

The committee ask us to aid them in bringing this matter before delegates intending to be present at the coming meeting, and in urging the adoption of the necessary means to this end. We do so with great heartiness, convinced that the plan of systematizing the work is an excellent one, and well calculated to meet all the possible requirements.

THE ADDRESS OF THE STATE COMMISSIONER IN LUNACY. We have referred to the fact that an address was delivered by Dr. Ordronaux, January 6th, before a distinguished audience, at the residence of Dr. C. R. Agnew. The earnest efforts which Dr. Agnew has made for a number of years to secure insane asylum reform, are well known, and have always invited our sympathy and commanded our respect. Hence we were led to expect that the call for the meeting referred to was of more than usual significance, and promised more than ordinary results. Perhaps because so much was expected, we realized our disappointment the more. We say this in all truth and charity towards our accomplished and esteemed friend, the Commissioner of Lunacy.

Dr. Ordronaux delivered an address which was learned and interesting, and marked by those rhetorical graces and felicities of expression which always characterize his remarks. He traced the origin of insane asylums abroad and in this country, and showed how much had been done everywhere for the insane, but more especially in New York. The amount of money expended in our State upon this class, and the perfection of the laws concerning the insane, were dwelt upon. The speaker concluded by saying that, as regards reform, none was needed, for there were no abuses to correct; or if there were a few in the county asylums, these could only be effected as the lapse of time brought about a change in public sentiment. Some very unpleasant things were intimated in regard to those persons who were ignorantly and hastily agitating the subject.

Dr. Ordronaux is a person whom official position gives weight to his words, and whose character raises him above all petty insinuations or attacks. But his statement that no reform is needed, that agitation is uncalled for, and that the agitators are either foolish or malicious, must naturally arouse some positive emotions of opposition. Have we, then, been mis-

taken in all our facts and statements? Did not our Governor condemn the extravagance in asylum buildings? Has not the Chairman of the State Board of Charities eloquently lamented the condition of the county insane? Could anything more scathing have been said by the English visitor to our asylums, Dr. Bucknill? If everything is perfect, why was a commissioner sent to Europe to study asylums there, and bring back advice and suggestions, which have not been acted on? In the recent message of the Governor to the State Legislature, he says: "The condition of the insane in the poorhouses of the State is pitiable in the extreme, and urgently demands attention." We heard nothing about this from Dr. Ordronaux. Does the commissioner wish the present mammoth asylum system perpetuated? Are acute and chronic cases still to be huddled together in vast colonies? He has admitted in his own reports that the number of insane in the State is increasing out of proportion to the population. Shall we make no changes for these in the future?

As for the imputations cast upon those who are seeking reform, there is no one whose reputation needs defence, and charges cannot be disposed of so easily. There is the best of evidence that the organization of insane asylums needs improvement, and that the medical treatment of the insane is not what it should be.

The question of the care of our insane is a very great one; it still needs discussion; there are problems in it yet to be solved, and changes in the present system that will have to be secured. Dr. Ordronaux made a mistake in substituting a historical review for a critical and practical discussion of the subject. The agitation concerning it has gone too far to be stopped by assuming indifference or attempting to ignore the points at issue. We admit him to be right in one respect—that he urges in an impassive way the stirring up of public sentiment, not the attacking of officials. This is the ground we have taken ourselves; but public sentiment will not be aroused by folding the hands and disclaiming all need of reform.

The best endorsement of the propriety of the recent meeting at Cooper Union, and of the necessity of further agitation, is this address by the State Commissioner in Lunacy.

THE SPREAD OF SMALL-POX.

It appears from our foreign and home exchanges that small-pox is more than usually prevalent in the larger cities of Europe and this country. Some of the statistics about the matter we have already given, but the prominence which the disease has gained requires further mention concerning it.

The history of the present extensive spread of small-pox goes back quite a number of years. About the beginning of the Franco-German war, according to the *Lancet*, small-pox broke out among the practically unvaccinated population of Brittany. While at its height there, conscription carried infected persons to the camps and introduced the disease into the army. From there it spread to the cities of France, notably Paris; and prisoners of war took the infection also into Germany. At the end of the war the general diffusion of men and material kept on the spread of the disease. During the years 1871–3, there were a great many cases in London, there being at that time large numbers of unvaccinated children in the metropolis. The disease has been gradually diffused over the whole globe; and, very possibly from the starting-point we have mentioned. Its prevalence in England has led recently to a great deal of agitation on the subject of vaccination, there being in that country a very pronounced feeling against it. This is, we are glad to say, outside of the medical profession. Statistics are brought forward to show that since the adoption of the vaccination act of 1867, the prevalence of small-pox has increased.

While some lay the blame for this increased prevalence to the radical inefficiency of vaccination, others assert that the lymph used has deteriorated in part, and in part has been genuine variolous and not vaccine lymph. The facts that we have given, however, and a general inattention to vaccination and revaccination, are sufficient to account for the condition of affairs. It is now sought to secure the compulsory vaccination of the populace with animal vaccine lymph; and although there is much opposition to this measure, it will probably be eventually carried.

During the past fall the disease seems to have received a new impetus; two hundred and fourteen deaths are reported from it in Paris since August, nineteen having occurred in the week ending December 13th; and more or less of the disease is present in Montreal, St. John, Havana, Belgium, Austria, Spain, Russia, and Morocco. Cases have occurred in the United States since November 15th, in New York, Philadelphia, Washington, and San Antonio.

Some of these latter cases it has been very difficult to trace. In most instances, however, where such tracing has been done, rags were found to be the carriers of the contagion. It is a peculiarity of small-pox sometimes to develop and spread in this insidious and apparently sporadic way. Therefore, although there are extremely few cases in the country now, it will be well for physicians and boards of health to attend promptly to the matter of vaccination. The proper authorities, also, should watch carefully the importation and inter-State shipment of rags.

A MALPRACTICE SUIT TRIUMPHANTLY DEFENDED.

The history of a malpractice suit brought against Dr. C. A. Robertson, of Albany, and recently dis-

ruined, has an instructive side, and we take the opportunity of referring to it. It appears that three years ago a certain grocer named Ives applied for treatment at the Charitable Eye and Ear Relief in Troy. He was found to be suffering with an old iritis, the pupil was entirely occluded, and the other so nearly so, that with the general dimness of the anterior media sight was almost entirely gone. He was told that an iridectomy might prevent the recurrence of the disease, diminish pain and give him a slight and only chance of securing better vision. Aware of the risks, he consented to the operation. A double iridectomy was performed with no difficulty or accident. Unfortunately a suppurative iritis followed, and the operation became, in consequence, a failure. The man, when the result expressed himself satisfied that all that could have been done for him had been performed. Last June, however, he brought a suit against Dr. Robertson for malpractice. It was attempted to have the trial in St. Lawrence County, among the friends of the plaintiff, and where the defendant, owing to sickness, would be unable to offer his medical testimony. This effort, however, was defeated; the case was assigned to the Albany Circuit Court. In that court the complaint was dismissed early in December last.

There were features in this case which unfortunately are too often found in suits for malpractice. The plaintiff was a charity case, a man to whom medical and surgical care had been given without fee. The plaintiff's lawyer was a young man, with a reputation for liking notoriety. We do not know that he was of that class which undertakes such suits on prospective fees, but it is a fact that such arrangements are often made. In the present case the circumstances were particularly unfortunate for the defendant, as he was sick in bed during the whole time. The opposing counsel was active in the prosecution of his work, and the future looked decidedly dark; but Dr. Robertson, believing it due to the profession as well as himself, to fight the matter out, did so, and with complete success. The courage with which, under disadvantageous circumstances, the cause of justice was adhered to and brought out triumphant, deserve great commendation; and it would be well if the practice of sticking to one's rights, instead of compromising to save trouble, were oftener adhered to.

PERCENTAGE ON PRESCRIPTIONS.

Our good friend, the editor of the *Michigan News*, appears to be backing water a little on the subject of percentage on prescriptions, but he has evidently not yet struck bottom. While condemning the practice of overtaxing the patient who is willing to pay for everything, he is in favor of making the would-be "dead-head" pay well for his medicine, so that there may be something of a margin for the doctor. But, in reality, two wrongs never can make a right. The physician, in such a case, is as bad as the patient, as both are acting under false pretences. The patient gets advice without intending to pay for it; the doctor obtains his percentage in an underhanded manner. If a patient cannot be made to pay for advice in any other way, he should not receive it. Then, again, the doctor should not tempt the patient to drug to become an inebriate.

GRATUITOUS SERVICES TO CLERGYMEN.

On a recent remarks upon the gratuitous services to clergymen are attracting considerable attention in our exchanges. The opinion appears to be quite unanimous in favor of charging fees to all clergymen able to pay them. Among others of our contemporaries, the *Buffalo Medical and Surgical Journal* is quite decided in its views.

"We fail to find any valid reason for these gratuitous services. The majority of the profession are members of, or attributes on some of the religious bodies, and share in the expense of their maintenance, paying their quota of the minister's salary. On what principle—certainly not of equity and justice—are they expected to dispense to the clergy, without compensation, the skill and knowledge acquired at a large expenditure of money, and of patient labor and effort, while the mechanic and laboring man enjoy no such exemption?

"Besides, it is a fact that services, thus freely and generously rendered, are but poorly appreciated by our clerical patrons. We do not approve of pauperization, whether among the genteel and educated, or among the ignorant and vulgar. No class of men, professional or otherwise, are beyond the reach of such demoralizing influences. We approve of a just compensation for the clergy, as well as for lawyers, teachers, and mechanics, and we especially endorse the apostolic injunction that the clergy should "owe no man anything," not even their doctor; "but to love one another," in which category we trust the profession of medicine, always abundant in good works in ameliorating the sufferings to which flesh is heir, may be included."

ADVERTISING CHARITIES.

The St. John's Guild is doubtless a very useful institution, and its work in supporting a floating hospital and a seaside home for children has been an excellent one. It is to be regretted, however, that it has to take such elaborate, and, we might say, fulsome methods of advertising, in order to support itself. The "Martha Washington Reception," a charitable entertainment given for its benefit, has full-column advertisements in the daily press. In these the good work of the Guild is endorsed by letters and by the signatures of about fifty of our leading physicians and surgeons. The case is further strengthened

by the endorsement of a dozen homœopathic physicians, whose names are placed, in a neat paragraph, below those of the regular fraternity.

It appears to us that a deserving charity should not require so expensive an appeal, or so elaborate an endorsement. "Good wine needs no bush." And when a cause has to indulge in an extent of advertisement rarely exceeded by that of a circus, it awakens uneasy feelings in regard to it. We say this not in any spirit of antagonism to the cause, but in justice to it and to those who would be more inclined to help if it were less ostentatious.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Dec. 18, 1879.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE Academy was called to order at 8 P.M., and the minutes of the previous stated meeting were read by the Secretary, DR. H. T. HANKS.

DR. MCFARLAND, U. S. A., was introduced to the Academy, and invited to a seat upon the platform. Under the head of "Reports of Sections," the secretary of the Section in Practice of Medicine, DR. KATZENBACH, reported that at the last meeting Dr. A. H. Smith was elected chairman, and Dr. J. N. Merrill, secretary, for the ensuing year.

THE FORCEPS [WITH A DEMONSTRATION OF THE TARNIER FORCEPS], VERSION, AND THE EXPECTANT PLAN IN CONTRACTED PELVES.

DR. WM. T. LUSK read a comprehensive paper upon the above subject, in which he touched upon a large number of questions which had a bearing upon the management of labor in three varieties of contracted pelvis: 1. The flattened non-rachitic pelvis; 2. The flattened rachitic pelvis; and, 3. The pelvis equally contracted in all its principal diameters. The intent of operative interference was to save the life of the child; for, with a dead child, version or forceps possessed no special advantage over craniotomy. There was no well authenticated case in which a living child had been delivered at full term through a pelvis the conjugate diameter of which is less than 2¾ inches. As a rule, no interference was called for with a conjugate diameter of 3½ inches and upward. The plan of his paper was as follows: 1. Every pelvis should be carefully measured, and the discussion should be limited to the management proper for cases of labor with pelves having a conjugate diameter between 2¾ and 3½ inches. 2. Having a pelvis of that size, a cervix fully dilated, a favorable presentation, and no complications, all statistics showed that, as a rule, it was best to wait, relying upon the expectant plan. Version, in contracted pelvis, was indicated only when the child was nearly in the normal condition, the antero-posterior diameter between 2¾ and 3½ inches, the contraction limited to the brim, and sufficient amplitude in the transverse diameter. The method of performing it was the same substantially as in a pelvis having the normal size. Reference was then made to the methods recommended by Dr. I. E. Taylor, of New York, and Dr. Wm. Goodell, of Philadelphia. Extreme traction force in version might result in fracture of the clavicle, or humerus, laceration of the sterno-cleido-mastoid muscle, rupture through the substance of the vertebral column, extravasations of blood into the tissues and cavities, springing the condyles of the occiput, disturbance of cranial sutures, fractures of the skull with depression of bone, rupture of intra-cranial sinuses with depression of bone. The records of competent operators were given, and showed for version a saving of 31 living infants in 43 cases, without the loss of a single mother; for forceps, high operation, head above the brim, 60 per cent. of children, and 40 per cent. of mothers perished; while by the expectant plan, out of 407 spontaneous deliveries there was a loss of only 53 children and 12 mothers by puerperal disease.

The field for version and other plans of treatment narrows itself down to cases in which the membranes are ruptured, the head above the brim, and the conditions such as render it impossible for the uterus to overcome the mechanical obstacles to delivery, provided the labor-pains are sufficiently energetic. After referring to different methods, he described the Tarnier forceps, with which he claimed to be able to bring the head of the child from the brim to the floor of the pelvis in much less time and with less expenditure of force than it can be accomplished by any other method. [For a description of the forceps of Tarnier and their mode of action, as presented to the Academy by Dr. Barker, see MEDICAL RECORD, vol. xii., p. 684.] Dr. Lusk had modified the instrument by having the blades modelled somewhat after those of the Wallace forceps, and by using a new lock for the traction handles. He had used the instrument in fifteen cases; it could be applied in any case in which Hodge's instrument could be used, and he was satisfied with the results. He was not, at the time Dr. Barker introduced the instrument to the Academy, prepared to accept it, but now he was sure that, by its aid, where the head was above the brim, he could deliver within a few minutes, where formerly, with the ordinary curved forceps, half an hour was required.

[The action of the forceps was then demonstrated upon the manikin both in a normal and a contracted pelvis.]

The paper being before the Academy,

DR. ISAAC E. TAYLOR remarked that while the field opened by Dr. Lusk's paper was a large one, and embraced many important and interesting questions, he should restrict what he had to say to a few points. He had had no practical acquaintance with Tarnier's instrument, but from its appearance and from what he had seen of it during the demonstration, he regarded it as essentially the forceps devised by Davis, of Dublin; for it had the same convex, concave, and anterior curves; also the same curve with regard to the handles, the fenestræ, and was such as was used more particularly by Meigs, of Philadelphia. He saw no reason why it might not be used as well as any form of forceps, yet he believed that, in the superior strait, they were not so good as the straight forceps. The main point, however, regarding any instrumental operation in midwifery was to know exactly what it was desirable to accomplish—exactly the work before the operator to be performed. The space to be operated in was very narrow. Dr. Lusk had placed it between 2¾ and 3½ inches conjugate diameter—only nine lines—in which the decision was to be made between version, the forceps, and the expectant plan. There was a vast dif-

ference of opinion among prominent obstetricians regarding the best method of procedure under such circumstances. In the demonstration which Dr Lusk had made upon the dummy that pelvis, the forceps were applied to the head of the child over the occiput and the face. There was a difference of opinion also as to whether the application of the instrument in that manner was the best, some favoring the method, and others, as Hodge, Wilson, and others, applying the blades directly to the sides of the head. Dr Churchill recommended to apply the instrument with one blade against the pubes and the other against the sacrum, but he Dr. T. did not believe any man ever had done the operation in that manner. Dr Taylor rejected or [illegible] the application of the forceps over the occiput and the face, and there was no advantage to be gained by so doing in a simple flat pelvis. More ample space could be obtained by bringing the coronal suture in contact with the promontory of the sacrum, and applying the forceps in the oblique diameter of the pelvis.

The head could be fixed in that position by the straight forceps; moderate compression was made, it was true, but it was not pressure antero-posteriorly upon the head—to which he was opposed under any circumstances—and was upon the parieto-frontal portion. The important point was to know how to handle the base of the skull, with the superior portion we had nothing to do; and unless the base was managed properly the forceps would not succeed.

If this particular portion came in contact with the sacrum and the straight forceps were applied, with the operator upon the floor making traction—we had an instrument that operated in the same manner as Tarnier's forceps, downward and backward, and with a to-and-fro movement according to the option of the operator. But suppose it did not yield? Version could then be employed. As to whether version should be attempted must be decided by the size of the child, size of fontanelles, etc.

With regard to generally contracted pelvis, he believed they were much more common than was usually supposed, and doubtless many cases of tedious labor depended upon that cause. The general contraction was perhaps no more than one-half or three-quarters of an inch.

In those contracted pelves he did not think that forceps should take the place of version in any case, or that version was more successful than forceps, simply because success had been obtained in special cases.

The chief point for discussion, as he regarded it, was simply whether with a head-presentation and dilated os in a contracted pelvis, it was proper to make the attempt to deliver by means of forceps. He did not object to the attempt, but after making two or three reasonable efforts, and failing, the instrument should be removed and version should be resorted to, aided by external pressure, which was of the greatest importance in this connection. He dissented *in toto* from applying the forceps over the occiput and the face.

Dr. E. H. M. Sell thought it important to regulate the method of management by the conditions in each case, taking into consideration the condition of the mother and that of the child.

Dr. T. Gaillard Thomas remarked that the only objection to the most excellent paper presented to the Academy by Dr. Lusk, was that it contained so little to be criticised. With regard to statistics, however, upon which the author had relied largely, he felt compelled to say that statistical evidence had but little weight with him. He was very often led to think of the remark made by Mr Sydney Smith in that connection—namely, "That there is only one thing more unreliable than figures, and that is facts." Every one who had ever been connected with a large hospital must know how loosely statistics were manufactured, knew very well how little reliance could be placed upon them.

He hoped he did not believe to that class of men who were biased in their opinions, and yet he must say that his convictions had grown stronger upon the question under discussion with his increased experience.

Let it be supposed we started with a case of labor with deformed pelvis—not a case in which the antero-posterior diameter was below two and three-quarters inches, when either the Cæsarian section or craniotomy was almost necessarily required—but a case in which delivery was to be effected either by natural forces or by the aid of science and art, without mutilation of the child's body.

In such a case expectancy, at the beginning, should invariably be practised; even though it was known that for the safety of both mother and child labor must be terminated by the use of the forceps. The forces of nature should be allowed to mould the head, and change its shape, and then the case might be brought to a most favorable termination; whereas a most terrible result might be realized if the case was approached too early with the forceps.

So long as the fœtal heart beat regularly, the maternal soft parts were moist and cool, and the pulse in the interval between uterine contractions not accelerated, we could with safety trust to expectancy. But expectancy which, up to that point, was a virtue, might soon after become a crime; and that was when it allowed the pulse to become rapid, the temperature to rise, the nutrition of the pelvic tissues to become impaired, the woman to be exposed to the loss of her life, or, if saved, to all the evils attendant upon vesico-vaginal fistula, sloughing of pelvic tissues, subsequent inflammatory action, and septic infection. But, coming to the case when it was in good condition, before expectancy had gone too far, the question arose, "Shall the woman be delivered by the forceps or by version?" There was no other operation at our disposal. Ergot, expression, or similar measures were of no avail; and the only means at our disposal to complete the labor *as required*, were those just mentioned. His convictions were these: If the uterus did not clasp the child's body so firmly as to render turning in its cavity exceedingly difficult, or the waters had not been so long evacuated that the result of turning, probably, would be a dangerous one from forcing the hand up to the fundus, with the head above the superior strait or entered into it to some degree, version, as a rule—to it there were exceptions—was the operation to be selected. Let it be supposed, however, that in attempting to introduce the hand into the cavity of the uterus it was found to be exceedingly difficult; suppose after carrying it in, the operator recognized that it was difficult to turn the child, the parts had become dry, and it was evident that the operation would prove to be one requiring a great deal of effort in order to complete it—then he should decide to discontinue the efforts at version and to try the forceps.

If the child had fairly entered the cavity of the pelvis so as to be fixed—was no longer a floating body above the superior strait; if what was difficult before had become unusually difficult—then the forceps was

the means which should be selected for completing the labor.

But, having elected which of the two operations should be adopted, version or the forceps, the operator was apt, in the hurry and excitement of the hour, to imagine that such decision was final. It should not be so regarded. Let it be supposed that the decision was to resort to the forceps, and they were applied, and from ten to twenty minutes, perhaps thirty minutes, were expended by the operator in exerting all his physical power for the delivery of the head; if the delivery was completed in that manner, the result was usually an evil one. Now, having decided to use the forceps, and having tried them fairly, having tested the question and found that so much difficulty arose, so great an expenditure of physical force was required, the decision should be reversed, the forceps withdrawn, and the operation of version substituted.

As an illustration, he referred to a case which the President and himself saw together. There was some contraction of the pelvis, and the woman had puerperal convulsions. One was in favor of using the forceps, and the other of resorting to version. The forceps were applied to the head at the superior strait, and all efforts at completing delivery failed. The forceps were then removed, the head was pushed up, the child was turned and delivered alive, and both mother and child did perfectly well. In that case it was not decided to adopt one method to the exclusion of the other, but the method which was first selected being tested and failing, the other was resorted to, and with a favorable result. In any case of deformity of the pelvis that should be the rule.

He thought the forceps of Tarnier was a great improvement upon older instruments, and believed that all obstetric instruments were susceptible of improvement, as were other matters in medicine; yet he did not believe they would ever get into general use. But, whether the forceps of Tarnier ever came into general use or not, he believed that in cases in which the head was at the superior strait, or just within the pelvis, they would prove to be an important and invaluable means for overcoming many of the difficulties in that class of cases.

Dr. T. C. Finnell believed that with a pair of ordinary obstetric forceps, such as Hodge's or Elliott's or Barnes's, all could be done that was required. Forceps were used too often. He favored conservative midwifery, and said, "Wait, wait, wait; Nature would accomplish very much if she was allowed to have fair play."

Dr. Paul F. Mundé said he should not like to wait, and wait, and wait; yet in every case interference should be of the most judicious character. He believed it to be generally accepted that the high-forceps operation was difficult, and liable to be attended by injury to the soft parts of the mother. Since the President presented Tarnier's forceps to the Academy, although at the time not favorably impressed with them, he had regretted that he did not have them at hand for trial, on account of the difficulty usually attending the high operation with the instruments ordinarily employed.

He raised the question whether the instruments devised by Cleeman, of Philadelphia, Vedder, of New York, Aveling and others, would not supply the place of Tarnier's forceps, and they were less complicated.

The President congratulated the Academy that Tarnier's forceps had been presented so much more effectually, and apparently so much more convincingly than they were presented two years ago. He then directed attention to a few points which he thought had not been emphasized either by the author of the paper or by the speakers who had followed him, as their importance deserved.

First, with regard to the vital condition of the woman as an element which should serve to assist in making a decision as to which of the two operations should be adopted, forceps or version. The point had been incidentally alluded to by the author of the paper, and also by Dr. Thomas, but was not made prominent. It seemed to him that there were certain principles which had a great guiding influence in deciding in any case, whether the forceps or version should be resorted to, and illustrated his position by giving briefly the history of two striking cases. Some years ago he was called to see a lady who had been in labor eight hours previous to rupture of the membranes, and fourteen hours afterward she was taken with convulsions, of which she had six in rapid succession, and was in a comatose condition when he first saw her. There was evident contraction of the antero-posterior diameter of the superior strait. The life of the child was of the greatest importance, on account of the succession to a large property. The patient was partially anæsthetized by the uræmic condition; furthermore, she had been under the continuous use of chloroform for six hours; therefore, the danger from shock would be only slight, and he attempted version, the head being at the superior strait, and only partially engaged. The operation was performed and delivery completed, the child was still-born, but was resuscitated at the end of two hours, and is still alive.

The other case was one in which the woman was in her second labor. In the first labor it was discovered that there was some contraction of the antero-posterior diameter, and the child was delivered after craniotomy. Before the second labor, she had made her husband and the physician promise that the child should not be cut to pieces, as she preferred, rather than to have the former operation performed, that she should be permitted to die. It was in 1862, and both physicians whom I met in consultation were strongly opposed to the use of chloroform. She had been in labor thirty-six hours, her pulse was quick and feeble, the vagina was hot, and her general condition was very bad. Dr. Barker thought the woman could not endure the shock of version, and proposed, and succeeded in persuading the gentlemen in attendance to allow him to administer chloroform, and attempt to deliver the woman by means of forceps.

In her general condition he regarded the forceps operation much safer for the mother than version. He applied the forceps, succeeded in delivering the child, which was still-born, and could not be resuscitated, but it was not mutilated.

He then recommended that, if pregnancy again occurred, labor should be brought on at the eighth month, which was done, and she was delivered by version of a living child, and both mother and child were still living.

The point which he wished to illustrate was that the vital condition of the woman should have great influence in deciding the question as to which one of the two operations, forceps or version, should be adopted.

RULES.

There were certain rules relating to these cases which he regarded as well established.

1. In that form of contraction of the superior strait called the oblique oval of Naegele's, the forceps should not be used, but we should always resort to version.

2. In that class of cases in which the contraction is at the inferior strait, with a straight sacrum instead of the normal curvature, narrowness of the subpubic arch, etc., we should never resort to forceps, but always select version, if we have the opportunity to make the election by a sufficiently early examination.

3. In face-presentation we should never resort to forceps when the head is above the superior strait, and not engaged.

He would not go so far as the author of the paper, and say that the forceps should never be applied when the head was not engaged at the superior strait, for he knew he had safely delivered several women, where it was necessary to save the life of the mother, when the head was not engaged at all, or was lying loose at the superior strait. But if the face presented under the same circumstances, we should not resort to the forceps.

He said, in at least three cases where there was a face-presentation in a contracted superior strait, and the face had become engaged in the strait, been successful in delivering by the forceps, by first flexing the head and converting it into a vertex presentation and partially rotating it. Then taking off the blades, he had reapplied them as if it was a vertex. In these cases it was fortunate that the original presentation was the face, because the vertex would not have engaged in these contracted pelves if it had presented.

Dr. Lusk, in closing the discussion, remarked that he had a little feeling of confidence in statistics, and he thought the result of the discussion showed that those which he had presented were not far out of the way.

He agreed perfectly with the President that it was possible to deliver with the forceps when the head was above the brim, and he only objected to the operation upon the ground that it was extra hazardous. Version, under such circumstances, was so much safer than the forceps, that he hoped it would be generally adopted.

With regard to Tarnier's forceps, he simply wishes that all who had the opportunity would try them, and that was all that Tarnier himself asked, for he thought they would prove of extreme service in difficult cases.

The President then announced the fusion of the Medical Journal Association with the Academy, and on motion a committee was appointed to see that the transfer was properly secured.

The Academy then adjourned.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Dec. 2, 1879.

Dr. J. C. Shaw, President, in the Chair.

The Society was called to order, and the minutes of the last stated meeting were read by the Secretary, Dr. Wm. J. Morton.

The Secretary also reported that he had, according to the instructions given him by the Society, at the last stated meeting, written three letters: one to the Consulting Board of Physicians and Surgeons, one to the Secretary of the Board, and one to the Board of Commissioners of Charities and Correction, and that to neither of his communications had he received any answer. The report gave rise to remarks, and Dr. Seitzka thought the inquiry had gone by default, because no attention had been paid to the correspondence from the Secretary, and advocated the adoption of the original resolution expressive of incompetence on the part of the Consulting Board to discharge the duties of such a board over insane asylums.

Dr. E. C. Seguin was opposed to the immediate passage of the resolution, and suggested that more time be given to the Board of Commissioners of Charities and Correction to answer the Society's proper request, made through the Secretary. On motion by Dr. Hammond, the further consideration of the resolution was postponed for one month.

New Members.

The Council reported for election as active members, Drs. A. Brayton Hall and L. Bradley; and as honorary members, M. Benvenisti, of Padova, Italy, and Prof. Diodati Borelli. The report was adopted, and the proposed candidates were elected.

Dr. Hammond presented a volume donated by M. Benvenisti, and the Secretary was instructed to return the thanks of the Society to the donor.

The Brain of a Porpoise.

Dr. E. C. Seitzka exhibited the brain of a porpoise with a view to the correction of certain errors that had been committed relating to the region in the brain which is supposed to preside over function of speech. It had been maintained for a long time, by some medical writers, that the island of Reil was larger in man than in any other animal, and, also, that it contained a greater number of convolutions, and for that reason the function of speech should be located there. But the reasoning was opposed by the facts. In the hippopotamus the development of the island of Reil was so great that, according to the theory, the animal should be entitled with complex symbols, if not gifted with the power of speaking. The island in the hippopotamus was homologous to that in the horse, and, the human and equine corresponding, it must be homologous to that in the human brain. Now, in the porpoise, the island of Reil had four times as many convolutions, and was twice as large as that in man, and was completely covered with by the operculum and temporal lobe. In the latter respect it corresponded to the anatomy found in man and the anthropoid apes.

Dr. Birdsall asked regarding the thickness of the gray matter, depth of the fissures, etc., and referred to the development of the island of Reil in the horse, which Meynert had made the basis of the opinion that the horse had good understanding, but could not evolve symbols.

Dr. Seitzka thought the horse a stupid animal compared with the hippopotamus, whose island of Reil was much larger than that of man, and yet the porpoise had a very much larger island than man, and a low order of intelligence.

Dr. L. C. Gray thought the association of function and localization was not so invariable as represented, and, to sustain the thought, referred to Claude Bernard's case, in which the patient had acute sense of smell without any olfactory nerve. He thought there were many exceptions to localization of function.

Dr. E. C. Seguin thought the fault did not lie in nature's laws, but in our deficient understanding of them.

Dr. Gray urged that what had been regarded as laws were uncertain.

Dr. Hammond took exception to the assertion by Claude Bernard.

Dr. Spitzka thought that, in the discussion, the bifurcation of the trigeminus had been forgotten, but Dr. Gray said it had not been overlooked, and Dr. Spitzka remarked that the essential oils were not recognized by the trigeminus.

THE HYSTERICAL ELEMENT IN ORTHOPÆDIC SURGERY.

Dr. Newton M. Shaffer read a paper on the above subject, and gave a detailed history of a large number of cases in which the hysterical element caused confusion in the diagnosis of affections of the joints. He expressed the opinion that many cases had been regarded by the "ordinary practitioner" as cases of Pott's disease, hip-joint disease, and knee-joint disease, that finally proved to be hysterical in character.

Discussion was postponed until the next stated meeting.

The by-laws were amended, so that the time for holding stated meetings is the *first Tuesday* in each month, instead of the first Monday, and the Society then adjourned.

ABSTRACTS OF MEETINGS OF FOREIGN SOCIETIES.

FRENCH.

ACADEMY OF SCIENCES.

December 24, 1879.. M. Danbrée, Presiding.

Mr. Brown-Séquard read a paper describing certain *experimental researches upon a new property of the nervous system.* These experiments were for the purpose of showing that there existed in certain parts of the nervous system a special property which in contrast to that producing inhibitory phenomena, manifested itself by causing a sudden augmentation of energy in the properties of other parts of the nervous system. The conclusion expressed by the professor was that there was a special property of the nervous system, by which certain centres under the influence of an irritation, caused, either suddenly or after a short interval, a notable increase in the motor or sensory activity of certain other parts of the nervous system.

M. H. Lenoir presented a paper on the alterations of the epidermis in affections of the skin or mucous membranes which tend to the formation of vesicles, pustules, and the production of false membranes. The microscopic changes which occur in these affections were described in minute detail.

ACADEMY OF MEDICINE.

December 9, 1879. M. Bouley, Presiding.

Dr. De Pietra Santa read a paper on *animal vaccination.* The great importance of animal vaccination and the degree to which the practice was already adopted in Russia, Spain, Austria, Germany, Switzerland, and the United States, were shown.

It was urged that arrangements should be made so that animal vaccine might be supplied to the citizens of Paris.

M. Peter communicated to the Society the first part of his researches upon local abnormal temperatures in diseases of the abdominal organs. He stated that in ascites the temperature of the abdominal wall was not raised, and might even be less than normal. In chronic inflammations of the peritoneum, however, the local temperature was raised a degree (centigrade) or more.

M. Hillairet said that he had made some researches upon the local temperature in skin diseases, but had not been able to arrive at any definite results.

M. Noel Gueneau de Mussey, referring to the statement of M. Peters, that he had used an ordinary thermometer in his experiments, described the surface thermometer devised by Dr. E. Seguin, of New York.

Dr. Onimus read a paper upon electro-muscular contractility and the action of curare. Contrary to the opinion of Cl. Bernard, Dr. Onimus believed that curare does not act on all parts of the motor nerves, but only the trunks, the nerve-centres and terminal filaments being unaffected.

SOCIETY OF SURGERY.

November 26, 1879. M. Tarnier, Presiding.

M. Gillette read a paper in which he showed the priority of M. Boucheron in the new operation for section of the ciliary nerves.

M. Boissarie reported the case of a patient who had suffered from a sanguineous tumor of the antrum of Highmore. It was at first taken for a nasal polypus. It was punctured, and the hemorrhage that followed could only be arrested by compression of the carotid. Tampons were applied also. At the end of a few days it began to suppurate, and the patient was announced as recovering.

M. Le Fort read a long paper upon Movement and Rest in Diseased Joints.

M. Le Dentu presented a patient on whom he had practised resection of the knee, removing six centimetres of the femur, and two of the tibia. The success was complete, the patient walking very well.

BRITISH.

ROYAL MEDICAL AND SURGICAL SOCIETY OF LONDON.

Stated Meeting, December 9, 1879. John Eric Erichsen, President, in the Chair.

Mr. Jonathan Hutchinson showed the body of a child, aged three months, in which *gangrene of the skin and body had followed vaccination.*

Three days after the vaccinia, vesicles had formed, and gangrene began to appear about them. This had spread slowly, and in three weeks the child was dead.

Mr. Hutchinson did not believe that there was any syphilis in the case. He had before seen such a condition follow in varicella, but never in vaccinia.

Mr. Henry Morris related two cases of *carcinoma of the breast preceded by so-called eczema of the nipples and areola.* Hitherto, no complete report of similar cases had been published, although Sir James Paget had, in 1874, pointed out the connection between the two diseases.

The reading of this paper was followed by a similar one on *Eczema of the Nipple and Cancer of the Breast,* by George Thier.

The pathological changes and relations of these two diseases were discussed.

The author believed that there was originally a slowly advancing cancerous change near the mouth of the lactiferous ducts, which, at a very early stage, led to irritative effects on the superficial tissues of

the nipple and surrounding skin and lymphatics penetrated into the substance of the mammary gland.

After reading the paper, Dr. Ebert demonstrated on cases of chloral drawings the differences between melanosis or duct cancer, and carcinoma or parenchymatous cancer. He also showed drawings of a peculiar case described by Dr. Foster in the New York *Journal of Dermatology* as one of melanosis. He regarded it as a new case of the affection of the skin which had been found associated with cancer of the breast.

The discussion on the two papers was postponed.

Correspondence.

CONCERNING MEDICAL FEES

To the Editor of The Medical Record

Sir:—If any practitioner with any business habit will sit down, and try to give to himself the reason for so many bad debts, he will, I have no doubt, be surprised to find how much such a state of things is due to downright carelessness on his part. The doctor is in the habit of dispensing his professional favors with a lordly hand, and, because his services are intrinsically above a mere monetary consideration, rather than demand his fee, and be particular in getting it, he will let it go. I have done so very often myself, and so have others of my professional friends. But it is all wrong. Many of our patients will find it to their interest to cultivate such a spirit in us by speaking of the great charity of the profession, the noble traits of its members, how valuable are the services rendered, what a Samaritan spirit actuates the doctor in helping his fellow-men, etc. In fact, the poor doctor is led, by such assertions, to believe that his principal vocation is to practise his profession on the poor, and thus get his reward hereafter. Every one wishes to have the reputation of doing good, but the profession of medicine has obtained such a reputation against very heavy odds. Our clergymen always speak of the noble, self-sacrificing spirit of the medical profession in a way that would make each practitioner envy the professional reputation of St. Luke, and emulate his example. But the clergymen themselves get our services for nothing, and their eulogia are very cheap, especially in connection with the fact that all their quack medicines are furnished them free for like services in attesting remarkable cures.

I have long since come to a business conclusion regarding this matter, and have insisted upon collecting every dollar I could from those who could and should pay. I do not except my minister from this class. I knew he was making twice what I did when I charged him nothing, and now, that the shoe is on the other foot, he is more content to pay for my services than he was to receive the same services before for nothing. I have every reason to believe that making him pay for my services has created this change.

I am of the opinion that we should not only do this way to clergymen, but every other class and condition of men concerning which and whom we give the benefit of the doubt in favor of free medical charity. You very properly say if we are not particular ourselves in demanding pay and in afterward collecting it, our patients become likewise indifferent, and think that our services are of small account.

I believe, also, that physicians are very apt to look over small accounts because in the first place, they are small, and secondly because the trouble of collecting them is more considerable than the accounts themselves. Here is a certain take. The man doing the largest trade will not hesitate to collect the smallest account. I am of the opinion that it would astonish the average practitioner how much extra comfort he could secure to himself by the collection of the smallest bills which he is so often tempted to neglect. With some it might amount to an extra horse, a new office desk, an extra easy-chair, a softer cushion, a warmer lap-robe, a new addition to his now too scanty library. The collection of the small bills which I was determined to get, paid for my Record for last year, and purchased a fine pocket case of instruments.

I always take a fee when it is offered, but I am daily finding out that I do not see to it that the fees are offered often enough. In France and England no patient leaves the office of the consultant and no medical attendant leaves the house unless the fee is paid. This is a custom of the countries and a very good one. I have long since ceased to think that the asking for money is unprofessional. "Short accounts make long friends," is as true regarding medical fees as any other.

I am well aware that it is fashionable to send accounts at the end of the year or half year only. This is well enough for the opulent practitioner, but rank to the younger and more hopeful members, of which your humble servant is one.

C. O.

Norwich, Conn.

To the Editor of The Medical Record

Sir:—I was pleased to notice that your editorial on fees took the ground that we should have a definite standard of prices, and that, having received the same, it is well to be satisfied. I am, I presume, not alone when I say that the really payment of a bill tempts the doctor into the belief that he should have charged more. I am sure that this is very wrong, and that the absolute standard of prices would correct it. In other words, we cannot afford to have two prices for our mental wares. I have had several patients of mine express surprise at the small amount of my bill, when in reality I expected they would find fault with me for overcharging. Of course I considered that I missed just so much by not charging more. But I further noticed that their surprise and gratitude never extended to the point of increasing the amount of the bill and writing me a larger check. Patients generally say they are surprised, but practically it amounts to nothing, at least they are never serious enough about the matter to come up to their pretended estimate of the value of our services. Hence I agree with you that some absolute standard of prices should be fixed, get all we can, but be satisfied when we do get it.

P. J. D.

Indianapolis, Ind.

To the Editor of The Medical Record.

Sir:—Will you allow me to say a word in regard to your editorial upon the subject of "Medical Fees"? I have recently had my attention called to a case that illustrates painfully the mistakes made by physicians in this respect, and I think that the stand you take in the matter is an excellent one. Physicians should pay more attention to the drawing up of their bills, and the settlement of their accounts. It is often

hrough this negligence that they become exorbitant n the one hand, or absurdly charitable on the other.

The importance of not changing the amount of a ill after it is once presented, should, I think, be ost emphatically insisted on. I was very glad to see hat you brought that point out with so much force. Every one has doubtless heard of cases illustrating he evils that result from the lumping and the discount policy.

I was told a short time ago of a physician who was alled in to treat a case of, I believe, chronic arthritis f the knee. The patient was a lady, and both she nd her husband were personal friends of the doctor. The case had been previously treated by another physician without success. The new-comer gave rather injustifiable hopes of certain cure in a given time; nd, I believe, even promised not to charge very much if he did not perform a cure. The case went n for weeks and even months; the patient, under severe counter-irritation, grew worse rather than better. At last the husband told the doctor that it did not seem worth while for further treatment to be continued; that his means were limited, and he really could not afford it. Thereupon the physician put in an itemized bill for a large amount, the items even including visits which had been announced as merely social ones. The patient protested, but the doctor insisted, and finally brought suit for the whole amount—about $250. After some consultation with the lawyers, however, he agreed to compromise, and took $100 in full for his services.

The whole story is very far from creditable to the profession, and it shows the necessity for doctors and medical societies to attend more closely to the ethical as well as business side of the question of medical fees. I hope that your editorial will stir up many on this subject.

M. S.

Brooklyn, L. I., Jan. 11.

HIGH TEMPERATURES IN NERVOUS DISEASES.

To the Editor of The Medical Record.

Sir:—In the report of a lecture by Professor W. H. Thomson, published in your issue of Jan. 3d, it is stated that in some nervous disorders the body temperature "has been known to reach 123° F., and remain there for several weeks." Will Dr. Thomson kindly give reference to the authority on which this statement is made?

Yours, etc.,

A. L. C.

TRACHEOTOMY WITHOUT THE TUBE.

To the Editor of The Medical Record.

Sir:—In a recent number of the Medical Record, I noticed that one of its contributors, in speaking of the operation of tracheotomy, asserted that a tracheal tube was no longer necessary, and that before many years it would be looked upon as a relict of the past. As this is a very important improvement, would the Record please invite some one familiar with this new mode of operating to give a full description of it? So far, the greatest difficulties inherent to the operation are attached to the use of the tube. Its introduction in the trachea, and to ascertain when it can be dispensed with, the irritation produced in young and irritable subjects, are all great barriers to its success, and prevents many a surgeon's having recourse to it. I am convinced that in three of my cases death was caused by the irritation of the tube, and lately I had a case which resulted in an erysipelatous inflammation of the wound, which came near being fatal.

Respectfully yours,

M. M. Metivier, M.D.

Mount Holyoke, Mass.

THE DETECTION OF STONE IN THE BLADDER.

To the Editor of The Medical Record.

Dear Sir:—Some months ago (September last), in conversation with Dr. E. W. Dulles, of this city, upon supra-pubic lithotomy, I mentioned a method of examination for "stone" which I felt confident would insure the detection, not only of those of medium size, but also very small particles, which would otherwise escape the notice of the examiner, through dulness of tactile sensibility in the fingers.

My plan was to lengthen the sound several inches, for reasons which will be at once obvious to you, and after inserting it into the bladder, grasp the end between the teeth, and make the exploration in the ordinary manner; or else attach wire to the sound, grasping it as before stated, and manipulating in the ordinary way.

If we consider the unerring sensitiveness of the teeth in the detection of a hair, or a very minute piece of grit between them, and also that the impression is conveyed to the ear by means of sound, we see at once that we have at our command two of the most trustworthy means of diagnosis, viz., tact and auscultation. A vibrating tuning-fork, placed upon the teeth, gives a shock which one is not apt to forget or likely to fail to hear, and so it would be in the case of a sound held between the teeth, and coming in contact with a roughened or hard substance, though perhaps in a less intense degree.

Having seen an article in a recent number of your journal, suggesting wires from the sound to the ear, I have been induced to communicate with you, though I intended to delay my communication until I had had an opportunity to make a practical test upon a human subject. I have had, as yet, no such opportunity, but a bamboo cane (three feet long), a bladder of water, and a stone, has convinced me of the increased perceptive sensitiveness of the teeth over that of the hand, and I offer the suggestion for what it is worth, in its crude and unverified form.

Very respectfully,

William D. Ronaldson, M.D.

Philadelphia, Pa.

THE PREPARATORY TREATMENT FOR OVARIOTOMY.

To the Editor of The Medical Record.

Dear Sir:—I herewith send you, for insertion in your columns, the report of a most interesting and successful case of ovariotomy, just sent to me by Dr. J. Williamson, of Ottumwa, Iowa. Considering the strong growth of the tumor, the size of it, the character and extent of the adhesions, and the eminently successful result of the treatment, I think the case cannot fail to interest your numerous readers. The principle of preparatory treatment, coupled after the operation with rectal alimentation and the continuous use of large doses of quinine and opium,

until all danger is passed. It is, I conceive, a most important case, if correct; and I think no case could be adduced that more strikingly illustrates the value than the one. Of the eight cases published by me in the Record, May and August, current series, with one of double ovariotomy since successfully treated, there is only one (Bridget D., that approaches in severity Dr Wilkinson's case, and yet his result is just as satisfactory as any of mine, without even the employment of the Lister spray of carbolic acid, to which I attached, in the treatment, much importance. If, therefore, further experience should teach that such results as this can be achieved without the trouble and disagreeableness of the Lister spray in the way here described, and by those the practice may be said to possess still more value, as I to prove a greater advance upon our former therapeutical resources than was first materialized by me in presenting it to the profession.

Yours very truly,

NATHAN BOZEMAN, M.D.

NEW YORK, Dec. 9, 1879.

The following is Dr. Williamson's letter:

DEAR DOCTOR:—Your articles on ovariotomy, published in the MEDICAL RECORD some months ago, very much interested me at the time I read them, especially your views on the importance of rectal alimentation and the anti pyretic properties of quinine and opium in the after treatment, used in the doses and manner there directed. It is because I think that the case I here bring to your notice goes far to confirm the correctness of your views that I have presumed to bring it to your attention at all. And let me say that neither experience nor operative skill (beyond that possessed by the average country doctor) had anything to do with the successful results of the case, having never made the operation but once before. I attribute the recovery of the patient to the management before and after the operation, and in this I followed your plan to the letter.

The patient was thirty-one years old; the tumor had been growing fourteen years. Ten years ago she was as large as a woman of eight to nine months' pregnancy. Of late years it grew slowly. Last January her physician tapped her and drew off *eight gallons* of fluid. In August following she was again tapped and five gallons removed. I was invited to see her, and requested to make the operation, and October 29th was fixed upon as the time. The preparatory treatment which you recommend was carried into effect for the week preceding the operation. On the day named the operation was made. Abdominal incision was seven to eight inches in length. The examination revealed extensive and firm adhesions. Sac emptied and closer inspection revealed that the uterus, intestines, omentum, were all extensively and firmly adherent; also numerous and strong ligamentous bands connected to the abdominal walls of the right side. Sac was removed by *enucleation*. By means of fingers, knife-handle and edge, and ecraseur, after sixty minutes of labor, the adhesions were detached, and the sac stripped, leaving an extensive area of denuded surface, with bundles of belts and ribbons stripped from the sac. Seven or eight vessels besides those of the pedicle were tied. Peritoneal cavity was thoroughly cleansed, and the belts of loose membrane carefully spread out. The wound was closed with carbolized silk sutures, dressed with cosmoline, cotton applied over abdomen, and a bandage over all, and patient then put to bed. Reaction was slow, for which I was glad, diminishing, as I thought, the risk of hemorrhage.

Now commenced the after treatment per rectum, as advised. I think you will agree with me that here was a case that would almost certainly become septicæmic, and that if it was carried through without becoming so, antisepsis would be entitled to great credit.

Fluid beef peptone and opium, per rectum, were administered *regularly*. Rectum remarkably retentive.

First ten days' average daily Quinine 45 grs.
" " " " " Tr Opium 6 drs.
" " " " " Fluid beef 10 ozs.

Very little by stomach.

Pulse during the time never above 100; temperature 99–100. 10th to 13th, rectum suspended. Pulse rose to 115, temperature rose to 102½. Quinine resumed in 10 gr. doses every six hours. Pulse dropped to 98–104, temperature dropped to 99.

From the time patient recovered rapidly, and twenty-eighth day after the operation walked out.

Now, Doctor, I think I am not over enthusiastic in claiming that antipyretic and supporting treatment saved this woman. I regarded the case as an unfavorable one for an operation, in view of the size of the tumor—fourteen years at least—its great size—estimated at sixty pounds—the extensive and firm adhesion. No antiseptic, except carbolized water (that is, Lister's *spray* was not used. No drainage tube was inserted (which I think was a mistake). The cyst was a simple, multiple, non proliferating cyst, thick and firm in texture.

Hoping I have not troubled you without cause,

I am yours truly,

J. WILLIAMSON.

DEC. 4TH, 1879.

ARMY AND NAVY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 4, 1880, to January 10, 1880.

HEGER, A., Major and Surgeon. To proceed, on or before February 1, 1880, to San Antonio, Texas, and report in person to the Commanding General Department of Texas, for assignment to duty. S. O. 3, C. S., A. G. O.

CLEMENTS, B. A., Major and Surgeon. Having relinquished his leave of absence, assigned to duty at Willett's Point, N. Y., relieving surgeon Anthony Heger. S. O. 3, A. G. O., January 6, 1880.

Official List of Changes of Stations and Duties of Medical Officers of the United States Marine Hospital Service, October 1, 1879 to December 31, 1879.

BAILHACHE, P. H., Surgeon. Relieved from duty, port of New York, and ordered to Philadelphia temporarily, thence to resume his duties as member of the National Board of Health, Oct. 25, 1879.

HUTTON, W. H. H., Surgeon. Relieved from duty, port of New Orleans, and ordered to Detroit, Nov. 1, 1879.

FESSENDEN, C. S. D., Surgeon. Relieved from duty, port of Portland, Maine, and ordered to New York, Oct. 25, 1879.

DOERING, L. J., Surgeon. Relieved from duty, port of Philadelphia, and ordered to Portland, Maine, Oct. 25, 1879.

AUSTIN, H. W., Asst. Surgeon. Relieved from duty, port of Key West, and ordered to New Orleans, Nov. 1, 1879.

Stoner, G. W., Asst. Surgeon. Relieved from uty, port of Buffalo, and ordered to Philadelphia. ct. 25, 1879.

Fisher, J. C., Asst. Surgeon. Detailed as Chair- an of Board for the Physical Examination of Can- idates for Promotion in the Revenue Marine Service, ov. 20, 1879. Granted leave of absence for nine ays from Dec. 19, 1879, Dec. 17, 1879.

Godfrey, John, Asst. Surgeon. Ordered to pro- eed to New Orleans, for temporary duty during ill- ess of Surgeon Austin, Dec. 29, 1879.

Goldsborough, C. B., Asst. Surgeon. Detailed as ecorder of Board for the Physical Examination of andidates for Promotion in the Revenue Marine ervice, Nov. 20, 1879.

White, R., Jr., Asst. Surgeon. Ordered to Buf- lo, Oct. 24, 1879. Orders to Buffalo, revoked; or- ered to report to Surgeon Fessenden, New York, r duty, Nov. 12, 1879.

Irwin, Fairfax, Asst. Surgeon. Upon expiration f leave of absence to proceed to Charleston, S. C., ct. 31, 1879.

Glazier, W. C. W., Asst. Surgeon. Relieved from uty, port of Charleston, S. C., and ordered to Key Vest, Fla., Oct. 31, 1879.

Cooke, H. P., Asst. Surgeon, Relieved from duty, ort of Pensacola, Fla., and ordered to Buffalo, N. ork., Dec. 1, 1879.

O'Connor, F. J., Asst. Surgeon. Ordered to Phil- delphia for temporary duty, Nov. 10, 1879. Ordered o Buffalo, N. Y., for temporary duty, Nov. 12, 1879. When relieved by Asst. Surgeon Cooke, to rejoin his roper station, Dec. 9, 1879.

Porter, F. D., Asst. Surgeon. Assigned to tem- orary charge at Detroit Marine Hospital, Oct. 25, 879. When relieved by Surgeon Hutton, to pro- eed to Chicago, and report for duty to Surgeon Mil- er, Dec. 17, 1879.

PROMOTIONS.

Austin, H. W., Surgeon. Promoted to be Surgeon rom Nov. 1, 1879. Nov. 3, 1879.

Gassaway, J. M., Passed Asst. Surgeon. Pro- noted to be Passed Asst. Surgeon, Dec. 12, 1879.

Smith, Henry, Passed Asst. Surgeon. Promoted o be Passed Asst. Surgeon, Dec. 12, 1879.

Stoner, G. W., Passed Asst. Surgeon. Promoted o be Passed Asst. Surgeon, Dec. 12, 1879.

RESIGNATIONS.

Ellinwood, C. N., Surgeon. Resignation accepted, o take effect Oct. 2, 1879.

Brown, J. A., Surgeon. Resignation accepted, to ake effect Nov. 1, 1879. Nov. 7, 1879.

Dana, C. L., Asst. Surgeon. Resignation accepted, o take effect Nov. 15, 1879, Nov. 11, 1879.

A Medical Scandal.—There is a wretched scandal about a physician in a neighboring city, who, by his attentions to a lady patient, excited, perhaps justly, the jealousy of her husband. The crisis came, final- y: the husband shot the doctor in the shoulder, and was himself shot in the hand.

From the facts so far given, the doctor was plainly in the wrong. We do not know how far. It is a disagreeable, but happily a rare duty, to have to chronicle such incidents. The education and the peculiar relations of physicians should make them the last to allow a disgusting sensuality to override the restraints of professional honor and social de- ency.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 10, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small pox.	Yellow Fever.
Jan. 3, 1880....	0	6	37	2	158	36	0	0
Jan. 10, 1880...	0	7	51	3	283	42	0	0

Charity Hospital, Blackwell's Island.—At the meeting of the Medical Board, held January 2d, at 12 West Thirty-first Street, Drs. Thomas R. Pooley and Charles Carroll Lee resigned as Visiting Surgeons to Charity Hospital. The Board of Commissioners of Public Charities and Correction has appointed Drs. E. S. Peck and John H. Swasey to the respec- tive vacancies.

New York Sanitary Reform Society. This so- ciety was organized on the 1st of December last, with the object of aiding in improving the sanitary con- dition of the city, and especially of the tenement- houses. The Society met Commissioners Chandler and Janeway on the 10th inst. and heard a report from the former upon the progress of the work of improving the tenement-houses during the past sum- mer. The provisions of the Tenement-house Act of last spring are now being strictly carried out. Builders are obliged to submit their plans to the Board of Health; at first, when this was done, changes had to be made in almost every case. Now the reverse is the rule, and both architects and builders are becoming satisfied with the new plans.

The various work of the past summer was detailed; but the facts have already been given in these col- umns.

Medical Society of the County of Kings.—The regular annual meeting of this society will take place January 20th. At that time there will be an election of officers of the society and of delegates to the State Medical Society. Reports of Committee on By-Laws and reports of officers will be made.

New York Academy of Medicine.—At a stated meeting held January 8th, Dr. Frank H. Hamilton was elected Vice-President; Dr. Edwin F. Ward, Recording Secretary; Dr. John G. Adams, Corre- sponding Secretary; Dr. Horace P. Farnham, Treas- urer; Dr. Wm. T. White, Trustee; Dr. M. Blumen- thal, Member of Committee on Admissions; Dr. J. C. Dalton, Member of Committee on Education; Drs. A. B. Judson, A. H. Smith, and V. P. Gibney, Mem- bers of Committee on Ethics; Dr. E. Darwin Hud- son, Member of Library Committee; and Dr. C. F. Billington, Delegate to the State Medical Society.

Report of the National Board of Health.—The annual report of the National Board of Health has been presented to Congress. It recites its work in the past summer; presents the data it has collected in regard to the best plan for a national public health organization, and concludes with a series of eight recommendations. These are:

1. That for the present no change be made in the organization of the Board.

2. That the Board be authorized by law to confer its powers and duties on an executive committee.

3. That the Board continue its special work of the investigation into the sanitary state of the Delta of the Mississippi, and that $50,000 be annually allowed for this purpose.

4. That the Board take steps to secure uniformity in observing vital statistics throughout the country, and that it call a convention for this purpose.

5. That the act to prevent the introduction of contagious and infectious diseases into the country have its scope enlarged and its penalties more definite, and that foreign consuls be detailed to give bills of health to vessels coming to our ports.

6. That the Board be empowered to report to the President when any locality is dangerously infected, and that, thereupon, interstate transportation, as regards that locality, shall be forbidden except under the rules of the Board.

7. That the President be authorized to call an international sanitary conference to meet at Washington.

8. That the Board at once establish quarantine stations near the mouth of Chesapeake Bay, at Brunswick, Ga., and near Ship Island in the Gulf of Mexico, these to be manned by the National Board of Health. The cost of these would be about $100,000. It is recommended that inspection stations for steamboats be established on the Mississippi river at New Orleans, Vicksburg and Cairo, the cost to be about $35,000. In regard to a refrigerating ship, it is not considered expedient that the contract for such a ship, if given, should be given to the lowest bidder.

The expenditures of the Board up to Dec. 31, 1879, were $154,002. For the expenses of the coming year it asks $180,300. It also advises an appropriation of $100,000 more, to be kept as a reserve, in case of emergency, and to be used in inland quarantine.

THE ANDIPHONE A FAILURE.—Dr E. T. Ingall states that Messrs. Sharp & Smith, of Chicago, have been testing the andiphone carefully for some time, and have not found patients benefited by it. Out of 150 successive cases of deafness, they report that not a single one noticed any benefit from its use.—*Chicago Medical Journal and Examiner.*

A NEW JOURNAL.—A new journal has appeared in Baltimore. It is called *The Practitioner*, and announces itself to be an independent monthly journal, devoted to medical, surgical, obstetrical, and dental science. It is to be edited by Harvey L. Byrd, A.M., M.D., and Basil M. Wilkerson, D.D.S., M.D. The contents of the first number are very good, and the typographical appearance of the journal excellent. We are inclined to criticise the name it has taken. There are now four journals having an almost similar title: *The Practitioner*, of England; *The American Practitioner*, of Louisville; *The Country Practitioner*, of New Jersey; and the journal now before us. The editor speaks confidently of the future, and we trust he will not be disappointed.

THE LIEUTENANT-GOVERNOR OF THE PROVINCE OF QUEBEC. The afore Robitaille, is a physician, who, though actively engaged in politics, has kept up his relations with the profession, and has been for years a governor of the College of Physicians and Surgeons of the Province of Quebec.—*Canada Medical Record.*

DEATH OF DR WILLIAM BUDD.—Dr William Budd, F.R.S., died at his house in Bristol, England, at the age of 69. Dr Budd has long been a prominent physician. He has been lecturer in the Bristol Medical School, and has written many scientific papers, the best known being that on Contagious Diseases.

DESTRUCTION OF OXYURIS.—Dr W. B. Dare reports several cases where he has used chloride instead of oxide, and has found it to produce marked contraction of the uterus. He asks for the experience of others in the matter.—*Medical Brief.*

HERMAPHRODITISM.—Dr Samuel Wolfe of Shippack, Pa., writes: A few days ago, I had the opportunity to inspect the genitals of an individual, who had reached the age of seventy-six, who, though he had dressed in male clothes, had been married as a husband and was entitled to the other social privileges of a male, had always been regarded by his friends and the community as an hermaphrodite. He was beardless, had a voice like a woman's, his habits and manners were effeminate, and his married life had been childless.

The genitalia, however, revealed nothing unusual except that there was congenital phymosis, only a sparse crop of very short hair, and a development in size, about equal to that of a boy of eleven or twelve.

Authorities teach us that true hermaphroditism consists in the possession of the distinctive organs of both sexes, in the same individual. The only organs that can be so regarded being the testicle and ovary; the testicle, according to Simpson, nearly always in the position for the right ovary, while the ovary is on the left. The external organs in these cases exhibit, to a more or less developed condition, both the male and female characteristics. True bi-sexuality in the human species, when judged by the criterion, is extremely rare, though of its existence there can be no doubt. There are, however, many persons, who, from a mere superficial examination, are with great difficulty referred to either sex. Many females, go through life in the character of males, while a probably lesser number of males are brought up as females. It is undoubtedly true, that a skilful scientific inspection, generally during childhood, and nearly always at puberty, would result in relegating these unfortunates to their proper sphere.

Not only every physician, but almost every other person, is acquainted with males and females who have the reputation of being hermaphrodites. Such errors arise, in many instances, from the personal manners and appearances of those whose married life remain unblessed by the birth of children, and is certainly favored by the carelessness and probably ignorance, with which medical men put technical terms into the mouths of the public. Such cases can, no doubt, often be found to correspond with the one I have described in the beginning of this article, and with us rests the responsibility of protecting these unfortunates. This is best done by teaching, when circumstances admit, the rarity of hermaphroditism; by never using the term, except when applying it to actual bi-sexuality; and by losing no opportunity to personally thoroughly examine individuals thus ostracised, giving to them a true statement of their condition, and of the place in society it fits them to occupy.

TO REMOVE PLASTER-OF-PARIS FROM THE HANDS.—Dr. T. E. Wilcox, Asst. Surgeon U. S. Army, writes: A little bicarbonate of soda or potassa added to the

water in which the hands are washed after applying plaster-of-Paris bandages, etc., immediately removes the unpleasant feeling left by the plaster.

Iowa State Medical Society.—The Twenty-eighth Annual Session of this Society will be held in Des Moines, Iowa, beginning January 27th, and continuing three days. Many interesting papers are promised. Reduction of railroad fare to and from the meeting can be obtained by addressing the Secretary, Dr. J. F. Kennedy, Des Moines, Iowa.

New York Laryngological Society.—At the annual meeting of the New York Laryngological Society, held at the Academy of Medicine, December 19th, the following officers were elected: President, Dr. R. P. Lincoln; Vice-President, Dr. Louis Elsberg; Secretary and Treasurer, Dr. William F. Duncan.

Small-pox in Washington.—The number of cases of small-pox in Washington, at any one time, has been from 15 to 20. Few new cases have been reported of late, and it is thought that the disease has ceased to spread. The work of vaccination has been vigorously prosecuted by the Health Department, 500 to 600 cases a day being attended to.

Death of Dr. David L. Eigenbrodt.—Dr. David L. Eigenbrodt died in this city, on January 3d, at the age of 69. He was born in Jamaica, L. I., and was educated at Columbia College and the College of Physicians and Surgeons. He practised medicine for some time in New York, being connected at different times with Bellevue, St. Luke's, and New York Hospitals. He had for many years retired from active practice.

Rapid Dilatation of Os.—Dr. J. W. Flynn, of this city, sends us an account of a case of puerperal convulsions in a primipara, in which a rigid os was dilated by the unaided hand, introduced wedgewise, in twenty minutes. The woman recovered, but the doctor's hand still aches.

Rectal Hemorrhage in Infancy.—Dr. J. A. McGuire, of Salem, Ohio, writes: In your Medical Record of September 27, 1879, I see an article on rectal hemorrhage in infancy. It is the first I have ever seen describing the lesion. The author suggests that it is of very rare occurrence, which induces me to report a case that came under my care, with much the same history. I was called, December 27, 1878, to see Mrs. R——, aged 22 years, in her first confinement. She was a healthy, vigorous woman, of short, stout build. On arriving at the bedside I found her in the first stage of labor, which was well advanced. Everything progressed favorably, and in about three hours she was delivered of a fine, plump male child, weighing about eight pounds. I called on the evening of the 28th, and learned that everything had gone well. The child's bowels had moved, kidneys had acted, and it had nursed. On the morning of the 30th, at 1 A.M., a messenger came for me in great haste, stating that the "child was bleeding at the navel." I hastened to see what the cause of the alarm was; on unwrapping it, I found that the hemorrhage was from the bowel, instead of the umbilicus, as stated. I estimated that about one and one-half ounces of blood had passed. I ordered that a solution of alum should be thrown into the rectum with a syringe, and in order to insure its retention, to hold a folded napkin firmly against the anus. I prescribed: R. Flu. ex. ergot (Squibb's), ʒ i. gallic acid, ʒ i. M. Sig. 10 to 15 gtts., in water, every one or two hours. I visited the child again at 1 P.M., learned that there had been two discharges of blood within the last twenty minutes. The child showed symptoms of exhaustion. I passed a gum catheter up the rectum four or five inches, and injected a diluted solution of liquor ferri subsulphatis, through it, by means of a syringe; ordered the patient to be wrapped in warm blankets, and wine to be given freely. After this the child seemed to revive—the pulse growing stronger. At 9 P.M., there was another discharge of blood, followed by cold extremities and more marked exhaustion. I packed the rectum with small tampons of cotton, saturated with the above styptic solution, continued stimulants, used friction to extremities, but at 12 M. the child succumbed, apparently from asthenia. On withdrawing the tampon from the rectum, a small amount of blood followed. There was no autopsy permitted. The author of the above-mentioned article suggests that if he had packed the rectum with cotton-batting and some styptic, he might have saved the life of his patient. As that line of treatment did not avail in my case, I am led to think that the lesion that led to the hemorrhage must have been higher up the bowel than Dr. Manly found in the case reported by him. He found an opening in one of the larger intestinal veins, situated about three inches from the anus, which admitted of the introduction of a bristle. It is possible that if it were proven by statistics that the lesion leading to such a fatal issue, as in the above two cases, was invariably situated within the reach of mechanical aid it might lead to the saving of life. I would be pleased to see other cases reported with results of autopsia examination.

Hydrobromate of Quinia for Hypodermic Use.—Dr. J. A. White stated to the Richmond Academy of Medicine that a solution of the hydrobromate of quinia was extensively used by Baltimore physicians for hypodermic injection. He had never seen it produce abscesses or local irritation, although he had used the equivalent of fifteen grains.—*Va. Med. Monthly.*

Apomorphia in Asthma.—One-tenth of a grain of apomorphia, injected hypodermically, will relieve the orthopnœa of asthma in a surprisingly short time.—*North Carolina Med. Jour.*

Health of New England.—The inhabitants of the Connecticut, Ammonoosuc, and Passumpsic valleys, from Massachusetts to Canada, have been unusually free from typhoid fever, diarrhœa, and dysentery during the year 1879. Diphtheria has prevailed fatally in many localities, especially in Vermont and New Hampshire.—*Boston Med. and Surg. Journ.*

Student's Societies.—There exist in Harvard and the Philadelphia medical colleges clinical conferences among the students of the graduating class. These meetings are considered useful to the students. We believe that among the 1,400 students in this city there are no regularly organized societies. If there could be some certainty that student organizations would not cultivate beer and tobacco, to the exclusion of medical science, we might expect much good of them. When students congregate, however, there is always a danger that a bibulous propensity will overcome professional enthusiasm. We advise students to be wary of organizing.

Medical School of Maine.—The vacancy in the chair of pathology and practice, occasioned by the resignation of Professor Palmer, has been filled by the election of Dr. Israel T. Dana, of Portland.—*Boston Medical and Surgical Journal.*

THE ELECTRIC LIGHT IN SURGERY.—On December 11th Mr Berkeley Hill operated before the Clinical Society of London at University College Hospital by means of the electric light. This consisted of a glowing platinum wire enclosed in a glass chamber, which was fixed enclosed in another glass cover. Between the two a current of water flowed. It worked very successfully.

QUARANTINE REGULATIONS.—A bill has been introduced in Congress, by Mr Ashley, of Louisiana, for the regulation of inter-State freight and passenger, and to remove the same from the restrictions of local quarantine.

DR. E. B. ALDECOTT.—Dr. E. B. Aldecott, Surgeon-General of Wisconsin, and a member of the Board of Managers of the National Soldiers Home, died of pneumonia at his residence, in the city of Milwaukee, January 6th, after an illness of a few days. He was seventy-five years of age, and was widely known throughout the Northwest.

HEALTH OFFICER OF THE PORT OF NEW YORK.—It is rumored that a nomination for Health Officer of the Port of New York will be sent into the Senate very soon. Dr Vanderpoel has held the place for eight years, and now some one else wants it. Dr. Wm M. Smith, of Angelica, Allegany County, is a reputed candidate. Gov. Cornell, however, is said to be a homœopathist in belief (it is probably his wife), and may nominate a gentleman representing that phase of psychological aberration. Dr Darwin E. Jones, of Albany, is reported to have the best chance.

"AND THIS IS ROME!"—Rome at present has a death-rate of 40 per 1,000, and is the unhealthiest city in the world, so far as is known, except Alexandria.—*Medical Press and Circular.*

STOKES ON THE CHEST.—The New Sydenham Society is to reprint the classical work of Dr. Stokes on Diseases of the Chest. Dr. Alfred Hudson is to be the editor.

PROFESSOR HEBRA.—The distinguished dermatologist, Professor Hebra, has been made a Hofrath, on account of the great service he has rendered to science.—*Boston Medical and Surgical Journal.*

INJURY OF EYES FROM CHLORAL.—Dr. G. W. Holmes, of New York, writes: "Noticing, in the Record of January 3d, a communication from Dr. Felton, Haverhill, Mass., that two cases of injury to the eyes, from the use of chloral, came recently to his knowledge, and asks, 'Has chloral ever before been known to produce a similar effect?' I would state during December last, I had under my care a very intelligent gentleman, from Alabama (cotton dealer), who occasionally took enough champagne, at dinner, to produce nervousness and loss of sleep. He stated his doctor frequently gave him chloral under similar circumstances, which acted nicely, except making his eyes very weak for several days, and requested me not to give it to him. After trying the bromides, the following night I gave him grs. xv. of hydrate of chloral (carefully disguising the taste) every two hours for three successive times, which had the desired effect of producing sleep; then followed the same painful eyes as on former occasions after taking the drug. He stated to me the next morning that there certainly must have been chloral in the medicine I gave him, as his eyes were very sore.

DEATH OF SOELBERG WELLS.—Dr. Soelberg Wells died at his home in London, Dec. 8th. Dr Wells was professor of ophthalmology in King's College, London, and ophthalmic surgeon to King's College Hospital and to the Royal London Ophthalmic Hospital, and author of a well known work on diseases of the eye. Apart from his professional attainments, Dr Wells was a man of the social qualities, and an excellent companion. He died while yet hearty and hale, only in his 48th year.

JOURNALS DEAD AND NEW BORN.—*The [illegible] Medical Review and Index, The London Medical Record, The National Medical Review, The New York Medical Journal, Sanitary Engineer, Public Health, Archives of Medicine, [illegible] Medical Herald.*

THE PHILADELPHIA ACADEMY OF SURGERY.—An application for a charter for a new medical and surgical institution has just been filed in the Prothonotary's office in Philadelphia, by A. Haller Gross, Esq., who represents the medical gentlemen instrumental in starting the enterprise. It is to be called the "Philadelphia Academy of Surgery," and the objects of the organization are the cultivation and improvement of the science and the art of surgery, the elevation of the medical profession, the promotion of the public health, and such other objects as may come legitimately within its sphere. With these purposes in view, when the Academy is established, a suitable hall will be selected where the members can meet at stated intervals, and read essays and discuss matters pertaining to medical and surgical affairs. The temporary officers of the academy are: President, Dr. A. Hewson; Secretary, J. Ewing Mears; and Treasurer, Dr Wm Hunt. It is expected that the building at Thirteenth and Locust, belonging to the College of Physicians, will be selected for the new academy.

The following gentlemen were the originators of the enterprise: Drs. S. D. Gross, D. H. Agnew, A. Hewson, J. H. Brinton, J. Ewing Mears, T. G. Morton, S. W. Gross, O. H. Allis, J. H. Packard, R. J. Levis, C. T. Hunter, Wm. H. Pancoast, H. Lenox Hodge, J. Ashurst, Jr., F. Willard, Samuel Ashurst, J. B. Roberts, and W. W. Keen.

A FŒTAL WALRUS.—At the last meeting of the Philadelphia Academy of Natural Sciences, Dr. Harrison Allen described a fœtal walrus which had been presented to the Academy some years ago by Dr J. J. Hays, who had brought it from the Arctic regions of eastern North America. The specimen is nearly three inches long, of a waxy white color, without the slightest trace of hair, and is nearly straight. This latter characteristic distinguishes it at once from the embryos of other carnivora. There is neither flexure of the head upon the trunk or the trunk upon itself. The limbs are closely folded upon the body. The muzzle exhibits the future position of the bristle by six rows of minute papillæ. The specimen is said to be unique.

HOSPITAL SATURDAY AND SUNDAY.—The collections for the hospitals on the last Saturday and Sunday of the year amounted to about $75,000.

BOOKS RECEIVED.

ANNUAL REPORT OF THE DIRECTOR OF THE MINT to the Secretary of the Treasury for the Fiscal Year ending June 30, 1879. Washington, D. C., 1879.

PHARMACOGRAPHIA: A HISTORY OF DRUGS OF VEGETABLE ORIGIN. By F. A. FLÜCKIGER and D. HANBURY, F.R.S. Second edition. London: Macmillan & Co. 1879.

Original Lectures.

A CLINICAL LECTURE ON THE TREATMENT OF LEUCORRHŒA.

By T. GAILLARD THOMAS, M.D.,

PROFESSOR OF GYNÆCOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

(Phonographically reported for THE MEDICAL RECORD.)

GENTLEMEN:—I want to make use of the cases that come before us to-day, not only to lecture upon their individual peculiarities, but to call your attention to one condition which exists to a greater or less extent in all of them, and that is leucorrhœa. You will find when you get into practice that these cases will annoy you more or less constantly, because of the difficulty in curing them. It is not with these cases as with those of phthisis, where you can assure your patient that she is improving under your treatment, and convince her of the correctness of your assertion. Here you cannot deceive her, for she has a better opportunity of deciding that question than yourself, and although you assure her that she is improving under your treatment, she is positive she is not one bit better than when she came to you—rather worse; and one of the miseries of the gynæcologist is to have some woman pestering his life, because he cannot cure her of her leucorrhœa.

I want now to refer to the several cases which I have selected for to-day's clinic. I have several times made the remark to you, that the man who does not practice surgery in gynæcology had better give up its practice entirely, for there are many cases where the use of the knife, even if it be only to a very slight degree, may effect a cure, where a prolonged course of treatment without it has entirely failed. I want to apply these remarks to some of the cases which come before us to-day, and when I speak of the use of the knife, I allude to it as a representative surgical instrument; scissors, the curette, and the pessary are surgical instruments, all of great value, but I speak of the knife as the representative of all instruments necessary for the proper treatment of these cases.

Our first patient, Mrs. Julia M——, is a native of Germany; has been married eight years, and has had two children and two miscarriages. Ten months ago she had a miscarriage, which was the last time she was pregnant.

Q. "How long have you been sick, madam?"

A. "I have not been well since I was fourteen years of age, but I have been much worse during the last ten months."

Q. "Have you ever been well since your miscarriage, ten months ago?"

A. "Not entirely well."

Q. "Tell us about your sickness."

A. "Two months after my last miscarriage I had a 'period' and began to flood; this continued twenty-one days."

Q. "And what then?"

A. "You took two pieces of the after-birth from me, and it stopped."

It seems that I saw her at this time, and now I recollect the fact that it was in consultation with her physician. I was asked to see her and found her blanched, with a small, feeble pulse and very weak, for she had flooded to a dangerous degree. The uterus was very large, and the view which I took of the case was, that the patient had some portion of the fœtal shell, for it could no longer be spoken of as placenta, left in the uterus, and that this flooding was a natural consequence of its prolonged retention. With the doctor's consent I made an examination, and convinced myself of the correctness of my first suspicion. I recommended the introduction of a sponge-tent to dilate the cervical canal, which the doctor did, and on the following day I removed from the cavity of the uterus two small pieces of the fœtal shell, each about the size of the distal phalanx of my index finger, and one day later the hemorrhage ceased.

Q. "Have you been well since that time?"

A. "Not entirely, for I have pain through my bowels, and am troubled a great deal with the whites."

We made an examination of this patient to-day, of course, and let me show you, upon the manikin, what I found. The uterus was quite large, something like the one I now place in position upon our model, and dragged down upon its supports so that the cervix had descended into the pelvis lower than it ought to be; and it is this condition which has caused our patient the pain and dragging sensation through her abdomen. Our patient says she has leucorrhœa, and now we want to talk of the method of curing leucorrhœa in her case. When I saw this case, eight months ago, there was no question about the loss of a large amount of blood. Her condition was a precarious one, and my attention, at that time, was directed to giving immediate relief. After I removed these fœtal-shell masses with a large curette, the hemorrhage ceased the next day, and I heard nothing further of the case. Since that time her menstrual periods have been, she now tells me, of only about two and a half days' duration. The uterus still remains large, swollen, tender, and heavy, and lower in the pelvis than normal. Now, what is the cause of it? This condition of the uterus is unquestionably the cause of the leucorrhœa, and the condition consists in what is commonly called subinvolution of the uterus; that is to say, the uterus has never returned to its original size since the miscarriage which occurred ten months ago. Now, what stopped involution of the uterus? Unquestionably the retention of these masses of placenta; there was no laceration of the cervix. These masses were retained in the cavity of the uterus for two months before any hemorrhage occurred. Their presence served to keep up a condition of passive congestion or subinvolution of the uterus, and this subinvolution affected not only the parenchyma of the organ, but also, as usual, the lining membrane became deranged, and in consequence thereof we have had a leucorrhœal discharge ever since. I believe if this patient were only put upon uterine and vaginal injections, it would be a long time before the leucorrhœal discharge was arrested; and it is very questionable whether she could ever be entirely cured by this means. But if we take this view of the case, that, owing to the presence of retained masses of the placenta, involution was prevented, thus giving rise to changes in the uterine tissue, and derangement of the mucous membrane, our treatment will be more intelligent and successful. I believe that this leucorrhœa could be rapidly checked by passing a curette up to the fundus, either after or before dilatation of the cervix (I do not think this case would require dilatation), and drawing it gently over both walls of the uterus. This process would probably

result in depriving ten or twenty little growths over the lining membrane of the uterus, that is fungoid growths which being removed, the leucorrhœa would rapidly disappear. Now, you might ask the question, and it would be a very pertinent question, Why do we not have bleeding if these fungoid growths are present? I answer, they may remain there a long time without the occurrence of hemorrhage, but hemorrhage is likely to occur at any time. This patient tells me that she carried two pieces of placenta in her uterus for two months after her miscarriage before any hemorrhage occurred, and in her present condition we may have hemorrhage coming on at any time. The point I wish to make is this, that in many cases of leucorrhœa you will accomplish more by one application of a dull wire over the lining membrane of the uterus, thus removing these little growths which keep up a flux of blood to the endometrium, than you could by any other plan of treatment. If this patient were under my care I would pass a curette cautiously and gently, but with sufficient force, to dislodge any of these fungoid growths on the inner wall of the uterus. After this I would keep her quietly in bed for forty-eight or fifty-six hours, watching her condition as to the occurrence of pain or increased temperature. After this I would support the uterus by means of a pessary, and why? Because it would be getting lower and lower in the cavity of the pelvis whenever the patient went about her work; or, if she were a lady of leisure, the same thing would occur when taking the necessary exercise for her health. Consequently, I would put the uterus in a sling to relieve the pain due to downward traction, and to diminish the congestion of the uterus by preventing its dragging upon the ligaments which contain its blood-vessels. Having removed the cause of the abnormal condition of the lining membrane of the uterus, I would put her upon ergot or viscum album. This viscum album I have been using considerably of late, and find it very efficacious in many of these cases. I would employ it in the form of the fluid extract, for the purpose of making tonic contraction of the uterus. If this did not work, or if it disagreed with the patient, I would give twenty-drop doses, three times a day, of Squibb's fluid extract of ergot, and, I believe, by this means, gradually the subinvolution would be removed, and her leucorrhœa would soon disappear.

Our next patient is Mrs. Catharine M. B——, a native of the United States, forty-nine years of age; has been married twenty-five years, and has had one child, but no miscarriages; her child is fifteen years of age.

Q. "How long have you been sick, Mrs. B——?"

A. "I have never been well since the birth of my child."

Q. "How have you been complaining during the last fifteen years?"

A. "I have pain in my back and in my groins; am very nervous, and cannot sleep."

Q. "Anything else?"

A. "I perspire a great deal."

You see, gentlemen, she looks very pallid.

Q. "How about your menstrual periods — have they stopped?"

A. "Yes, sir, some years ago."

Upon feeling of her pulse, I find it excessively weak. She looks like a woman who has some serious organic disease, some pulmonary or renal disease, or something of the kind. She looks older than a woman of forty-nine years. She suffers from leucorrhœa. I have picked the cases which I present to you to-day, so as to call out the treatment of leucorrhœa. If you are going to encounter cases of leucorrhœa — and these cases will follow you throughout your practice as gynecologists — you must persist in trying to get at the cause of each case, and although this will not be possible in many instances, and you will find cases which will battle all treatment, nevertheless it is the plan to be adopted as offering a clearer insight into the pathology of this class of cases. Now, what is it that is impoverishing this patient's blood? Very likely the leucorrhœa has a great deal to do with it. The leucorrhœal discharge continues, although she has passed her menopause. She is thus losing a large quantity of the albuminous portions of her blood, in consequence of which her nervous system has become depressed. Her appetite is poor, and although I have not inquired in regard to her bill of fare, I think it is not a very prolific one.

Q. "What do you eat for breakfast?"

A. "I do not feel like eating much in the morning. I usually take a little bread and butter, with perhaps some preserves and coffee."

Q. "When do you eat your next meal, and of what does it consist?"

A. "I usually do not get hungry before three o'clock in the afternoon, and then I generally eat a small piece of beefsteak, together with bread and some vegetables, as canned corn, turnips, or potatoes."

Q. "When do you take your next meal?"

A. "I do not dare to eat much at night; I usually take a cup of tea, together with bread and butter, and some sort of sauce."

Q. "And is this a fair specimen of your daily diet?"

A. "Yes, sir."

Well, gentlemen, I have nothing to say about that bill of fare, other than I think every student of medicine, after graduating and before entering upon practice, should be kept upon it about two weeks, so as to impress upon his mind how these patients are kept sick. Just compare that bill of fare with what a man in active life eats; compare it with what an ordinary woman in active life should eat. You must remember that in this country this system of starvation is more general than in any other country. If you were to travel in England you would find no such bills of fare as this. The people there eat four or five meals a day, and of the most nutritious food, drinking a great deal of beer and wine.

Q. "What wine do you drink?"

A. "I do not take any stimulants whatever."

Now, the Americans, I think, have the misfortune of being the most temperate people in the world. The laboring classes do not take enough food and drink to sustain them in a condition of health. I am talking of a class, and not of the exceptions. The diet of American women, as a class, you will find is fairly illustrated in the case before you. You know we read of the rosy-cheeked, strong, and buxom country maiden, so frequently described by old English writers; but go into the farming districts in America, and do we find them? Not a bit of it. They live upon the same kind of fare as this patient, and in our country homes you will find women pale, lank, and showing absolute want of nourishment. Remember, I am not speaking as a reformer, but as a physician. If you want to cure these patients, you will have to commence in the kitchen, and make them eat more food, and of a more nutritious nature.

Unquestionably, one of the strongest points in favor of the "rest cure," introduced by Weir Mitchell, of Philadelphia, is, that these patients are fed every two hours. They all go there more or less starved; but, should one come there not in a starved condition, Dr. Mitchell would not submit them to this plan of treatment. One who is starved, immediately begins to improve under this course of treatment. But we have another element to consider in our present patient's case, and that is starvation due to loss of albuminous portions of the blood by this leucorrhœal discharge. I wish to impress upon your minds, that one of the most important elements of treatment here is to feed this woman properly. If her diet were changed, and she were to eat fresh meat three times a day, together with other food, and between these meals take a tumbler of fresh milk, thus making six meals a day, if she were given iron, bitter tonics, beer, and ale, in addition to all this, we would find our patient changed entirely for the better in one month. This system of feeding up is what improves patients largely in our well-regulated hospitals. Very often the improvement in hospital patients is considered by the attending physician as due to the administration of remedies which he has recommended, when in reality it is owing to improved nutrition. I have not time to go into details concerning the diet of these patients, but I have told you enough to make you think for yourselves.

We must stop this leucorrhœal discharge; but how are we to stop it? Look at this patient and tell her that she is suffering from anæmia or spanæmia, and put her upon iron, quinine, and good diet, and send her away, at the same time telling her to avoid all local treatment. That is all nonsense, as hundreds of medical men who are to-day talking in this ridiculous way to their patients, follow that plan, and this patient will never get well, for you are pouring water into the mouth of a hogshead and leaving a spigot open below. As long as you allow this constant leakage of the albuminous portions of the blood, your tonics and nourishing food will fail to effect a cure. Now, let me tell you the result of my examination. I placed the patient upon her back, passed my finger up the vagina, and at once discovered a polypus hanging from the mouth of the womb. Iron and quinine will not remove that polypus nearly as well as a pair of scissors. If that polypus were snipped off now with a pair of scissors, we would be removing the cause of the discharge. It is called a cervical polypus, and is attached at the os internum. I suppose that polypus has been there fifteen years, or at least for several years—that is, I think it highly probable, for the leucorrhœal discharge has existed fifteen years, and there is nothing else the matter with this woman's genital organs. If that polypus were removed, the leucorrhœa would be removed, and she would not lose so much of the albumen of the blood every day. This little mass is constantly moving like the clapper of a bell, and every time she gets up, every time she respires, it is rubbing against the endometrial wall. This polypus ought to be removed, and the patient ought to be treated in a general way. By so doing, I believe, as in the case which preceded, she might be entirely cured. You can scarcely believe that this is all that is the matter with the patient, nor can I; but I do believe it, just as you believe it. Very often the physician is inclined to overlook a little thing like this, just as the leper of old was inclined to overlook the river Jordan as a means of becoming purified.

As I was going to say, suppose I remove that polypus, and suppose I cure the leucorrhœa, then I will have accomplished what the patient desires, and afterward I can repair the damage which has been done her system, not only by this, but by diet and tonics.

Our next patient comes to us from a distance. Mrs. Caroline R——, a native of the United States, has been married nineteen years and borne nine children, and has had one miscarriage, which occurred at her last pregnancy, a year ago, since which time she has not been well.

Q. "What is the matter with you, madam?"

A. "For a year I have felt as if there was something wrong here in my left side."

She tells us that after her miscarriage a year ago, she had a flooding which prostrated her very much, and when she got up from this she lifted a heavy stove, and as she did so she felt something give way. To this she attributes the dragging sensation which she has experienced in her left side ever since. She says she feels very weak; that she has considerable pain, and that her bowels are constipated. You observe that this patient seems emaciated. She says she has been thin for several years, but never so much so as within the last year. Of course I at once proposed an examination, and found the vaginal canal bathed with leucorrhœa. You may say, do all these cases have leucorrhœa? Many of them do, but I have intentionally brought these cases before you to-day to impress upon your minds the fact that that condition which gives rise to leucorrhœa, and in consequence of which we have a flux of blood to the lining membrane of the uterus, can often be relieved by surgery. Upon examination, I found that the uterus had descended so as to project into the lower part of the vaginal canal, and this explains why she experiences a dragging sensation in her left side, but why it is confined to the left side I do not know; probably because one of the broad ligaments is more sensitive to pain than the other, but why more sensitive I do not know. But now, to go a little farther: passing my finger up to the cervix, I found it torn to a little extent upon one side, and the mucous lining everted. Leucorrhœal material was pouring out of the uterus itself; it was not at all vaginal. The patient is very uncomfortable, very much run down, and this constant leucorrhœal discharge is sapping her strength. I will not stop to go over her bill of fare, but, from my knowledge of these cases, I am willing to take it for granted that it is about the same as in the other instance. Looking at her face, one would say she is certainly not a well-nourished person. In regard to this symptom, which is constantly robbing the blood of important elements, put this patient upon iron, quinine, and a good diet, together with vaginal injections, and send her home. Three years hence, if you see and ask her how she is, she will tell you she is a good deal better, but you did not cure her of the whites, and why? Because you have not touched that part of her case at all. Now, as in the first case, where the cause of the continuance of the leucorrhœal discharge, that is, fungosities upon the endometrium, with subinvolution of the uterus, was different from the cause which prevailed in the second case, namely, a polypoid growth in the cervical canal, so in this case there is an entirely different cause from that in either of the preceding cases, and that is ectropion of the lining membrane of the organ. If you will absorb the idea that to be a good gynæcologist you must be something of a surgeon, and if in this case you will simply snip this ectropion on each side and

tion in the edges of the mucous membrane, you will cure this patient of leucorrhœa within two weeks after the operation, or certainly within four—not by any other treatment, but simply by removing the cause of the leucorrhœa, which, as I have already stated, is a slight laceration with retroflexion. But when this is removed, will the patient be well? Not by any means. The vagina is lax, the perineum is worthless and in a state of relaxation. The traction on the posterior wall of the vagina may be overcome by means of a pessary, and a great deal can be done by the use of astringent vaginal injections, thus keeping the vaginal walls contracted. But repair of the perineum will do more toward the cure of the case than anything else that could be done.

Our next patient is Miss Julia B——, who comes to our clinic to-day in company with her mother and aunt. She is a native of the United States, and is unmarried. She has been sick for six months.

Q. "Will you tell me whether you were in good health up to six months ago, miss?"

A. "Yes, sir, I was."

Q. "How have you complained during the last six months?"

A. "I have had a severe headache."

Q. "And how about your monthly sickness?"

A. "I have not had my periods for six months."

She tells us that she is troubled with backache and occasional rushes of blood to the head. She has also had the whites for a considerable time. Gentlemen, the case is before you; I will not add to the symptoms. Now, let us suppose you were in your office, not in the lecture-room of the College of Physicians and Surgeons, and just beginning practice, say next April or May. It is very important that you do full justice to all your cases, and equally important that you do justice to yourselves. The diagnosis here is very important, of course, and you have to be exceedingly careful to arrive at a correct one for many reasons. In the first place, you may, by not doing so, damage your patient, and in the second place, by not arriving at a correct diagnosis, you would fail to cure the patient now before you. When a patient with a history like this presents, of course certain thoughts pass through your mind. One would perhaps be, is this a case of amenorrhœa occurring in a young woman otherwise healthy—amenorrhœa from some unknown cause, perhaps from some nervous state; and this amenorrhœa would perfectly account for her symptoms—the rush of blood to her head and backache, which is increased in severity at those times when she ought to menstruate, etc.? Well, you may accept this theory, but be careful how you act upon it. I proposed a more thorough investigation in this case, and the patient at once consented to an examination into the condition of the pelvic organs. I discovered an abdominal enlargement extending up to the umbilicus. In some cases of amenorrhœa you will find abdominal enlargements, and these are most commonly in hysterical patients, and hysterical patients almost always have tympanitis; so there is nothing remarkable about the fact that an abdominal enlargement exists. I proceeded to investigate farther, and placed one hand upon the surface of the abdomen, and with the other percussed, expecting to get a drum-like sound, but I did not. The sound elicited was of something solid, and so I said to myself, this is not hysterical tympanitis, for there is no drum-like resonance. At once vaginal touch was practised, and the cervix discovered to be soft, with the os dilated. Now, other diagnoses presented themselves to view, and I began to feel that it was one of those cases in which a mistake would be particularly disadvantageous both to patient and physician. In your office it would be much easier to than here at a college clinic. Is there any way by which we can arrive at a certain diagnosis in the case? She has been amenorrhœic for six months, and the best way of arriving at a correct diagnosis under these circumstances is to place your finger upon the anterior wall of the uterus, just above the os internum, and push upward, and if you feel a round hard mass lifting itself up and dropping upon your finger, then you can be almost absolutely certain of your diagnosis, because there is only one other condition which gives you this, namely, abdominal dropsy, with a small fibroid rolling around in the abdominal cavity, which, when you press it up, rolls about and drops upon your finger. I have had two cases of this kind in my own experience. Cazeaux declares he has seen a case of an anteflexed uterus giving this sign. I have never seen such a case. Examination of the cervix revealed softness and enlargement of the canal, and, in addition, we have the usual mammary and gastric signs, and our diagnosis is complete. (Exit patient, mother, and aunt.)

I have tried to deal as much as possible in technical terms while speaking of this case, so as not to embarrass the patient, or her mother and aunt. The young woman is six months pregnant, and is just as innocent of the knowledge as you were when she came into the room, and she is still the same way, for all that I have said is as Hebrew to her, her mother, and aunt. I am as sure that there is a fœtus in the uterus of that young woman as I am that there are a certain number of gentlemen on the benches in this room, and that that fœtus is about six months old. Without expecting a confession, at my request, after the girl went out, Dr. Hunter told her that she was pregnant, and asked her if she had been exposed, to which she replied, yes. She is a *rara avis*, she tells the truth! You remember I told you you would have to be very careful how you announced your diagnosis in such a case as this. You are sitting in your office, and you are just about as sure of your diagnosis as I am of mine, and perhaps it is one of the first you have made, and on that account you are all the more anxious to announce it; but be careful how you do, for in all probability your patient will assume to get excessively angry, and denounce you as an unjust accuser; her father, mother, and all her relatives will do the same; they will take it as a matter of personal insult. They will do this when they know you are telling the truth. The girl will be spirited away for two months or so, and when she returns she will come back to you and will tell you that you made a horrible mistake, and nearly ruined the family; that she has been examined by other physicians, perhaps by some in your own town, who will rather be delighted with the opportunity of saying that she is not pregnant. This may be so now, but she was pregnant when you examined her. Beware of it! The case we have seen to-day is a rare exception to the general rule, for you will find ninety-nine women out of every hundred will swear to the very last that they know nothing of the matter. One of these cases came under my notice some years ago. I made a diagnosis of pregnancy in a young woman from the lower walks of life, but she declared that it was preposterous, that it was not possible for anything of the sort to exist, as she had not been exposed in any way. She was so violent in her assertions that I accused her falsely, that I felt it my duty

to defend my position. At my instigation she entered Bellevue Hospital, and when she was confined I was present and delivered her. When the child was born, and while yet attached to the placenta by the cord, I said to her, "Do you confess?" She replied, "No, I do not; you put that child there."

Now, gentlemen, as physicians you must protect yourselves as well as possible against the occurrence of such complications as I have just detailed. You may ask how is this to be done? It is a little difficult to answer; but I would say, if you are a beginner, and cannot stand upon your own merits in the case, it would be best, before announcing your diagnosis, to have a consultation, and commit some other man to the same diagnosis to which you have been committed. By so doing you will fortify yourself against attacks which would otherwise prove damaging to your professional reputation.

Original Communications.

TEA-TASTERS AND THE HEALTHFULNESS OF THEIR PURSUIT.

By C. L. DANA, A.M., M.D.,

NEW YORK.

A VERY interesting paper was read before the American Neurological Association last summer, by Dr. W. J. Morton, on the subject of the toxic effects of tea. In it he referred to the practice of tea-tasting by brokers and others engaged in the tea business. From an examination of the subject, he was led to the conclusion that the business was an unhealthy one, and that few could carry it on many years without breaking down. These statements were brought to the attention of a gentleman engaged in this pursuit, and were promptly and emphatically contradicted by him as entirely unfounded. I subsequently met a number of other tea-tasters, and they very courteously gave me their opinions and experience in the matter. These are detailed below.

Some facts may, in the first place, be given in regard to this practice of tea-tasting. There are, probably, more than a hundred firms engaged in it in this city. In all of their offices there are large tables with round, revolving tops. A circle of tea-cups is placed along the edge of these. The tea-taster sits down before the display of crockery and tastes one cup after another, moving the table-top around. In the centre of the table is a pair of scales with a silver half-dime in one of the balances. One or two large kettles are kept constantly with boiling water in them. When a sample of tea is to be tasted, as much is weighed out as will balance the half-dime. This is put in a tea-cup and the boiling water poured on. The tea-taster then stirs up the leaves, lifts them on his spoon and inhales the aroma. At the same time he generally takes a sip of the infusion, holds it in his mouth for a short time, and then spits it out. Enormous brass cuspadors, holding two or three gallons, receive the tea thus tasted and the contents of the cups that have been examined. On some occasions, when a large amount of tea of a certain kind is to be bought, many samples of this are brought in from different houses. The buyers and sellers sit around the revolving table with the samples made into infusions in the cups before them. These are tasted all around, the "body," fineness, "toastiness," etc., are learnedly discussed, and the poorer specimens discarded. Then those that are left are tasted again and the number further reduced. So it goes on until the article which unites the desired quality and price is obtained.

The skill displayed at these "drawings" is quite remarkable. A tea-taster will detect not only the quality of a tea as regards age, strength, flavor, fineness, etc., but he can tell in which of the numerous districts in China the tea was grown. The facts regarding the different samples are sometimes put on the bottom of the cups, where they cannot be seen. The cups are then mixed up, and the infusions tasted again and sorted out simply by their flavors.

A great deal of tea may be tasted before these tea-drawings are finished. It is hard to tell the amount that a tea-taster takes during a day, for it varies a great deal with the activity of business. Few of the gentlemen whom I asked could give any idea. Sometimes, however, as many as four or five hundred cups are tasted in the day. It is quite the custom to have to be tasting tea steadily for the most of the day, or for hours at a time. Probably an average of two hundred cups a day throughout the year is a low estimate. The poorer kinds of tea are often not sipped at all, but the sense of smell is depended on. Of the better qualities of tea, some is swallowed, and some spit out. Indeed, whenever the tea is taken into the mouth, a little of it is swallowed. The tea gets into the system, therefore, in three ways: by inhalation, by absorption through the oral mucous membrane, and by the stomach. More tea is simply taken into the mouth without swallowing than is inhaled alone; but all the tea is inhaled, even if it is tasted also. It is only a small proportion, amounting to not more than two or three cups a day, that is swallowed. A silver five-cent piece weighs 1.18 grms. (gr. xviii.). Estimating that an average of 200 cups of tea are tasted per day, about one-half of a pound would represent the whole amount used. If I remember correctly, one tea-taster informed Dr. Morton that he got about half a pound of tea into his system every day. This is too large an estimate. It is not likely that more than from one to two pints of the infusion are taken into the mouth during an average day's work. To this must be added the volatile oil which is inhaled and absorbed.

I will now briefly relate the cases which I have collected.

CASE I.—S. W. G., a gentleman about 60 years of age, has been a tea-taster continuously for 33 years. Tastes 300 or 400 cups a day; on "cargo" days much more. Has always been well; experiences no effects after tasting tea all day; did not feel any bad effects when he began in the business; in fact, he suffered from dyspepsia before he entered it, and after that the symptoms left him entirely. Is temperate; thinks that Japan tea affects the kidneys somewhat, causing increased flow of urine. Formosa teas sometimes do the same. Thinks that tea-tasters are, as a rule, healthier than men in other branches of trade.

When he began tea-tasting, it was the custom to chew the leaf; or to blow on it, and then smell the aroma which the moist breath developed.

CASE II.—J. S. C., age about 60, has been a tea-taster 38 years; is a strong, healthy-looking man; never has experienced any ill effects, either immediate or secondary, from his habits; uses tobacco. His other statements correspond with those of Case I.

CASE III.—B., age about 55, has been a tea-taster 35 years; is perfectly well; is temperate; uses to-

bacco. This and the succeeding cases agreed in their statements, except where specified, with Case I.

Case IV.—J. M., age about 60; has been a tea-taster 37 years; is perfectly well; uses alcohol and tobacco. Occasionally, after a long day's work, feels nervous, and thinks that sometimes he has been kept awake by the tea, otherwise he has never felt any bad effects from it. Drinks it at home.

Case V.—Brother of Case IV., age 73; has been a tea-taster 40 years; is still in excellent health.

Case VI.—This gentleman I did not see, but was told that when he began to taste tea he suffered for a time from dyspepsia and "sour stomach," but is now perfectly well. This case was that of a younger man.

Case VII.—J. O., age over 50, tea-taster 30 years, during that time he had a sunstroke, and suffered from after-effects. Has not been injured by tea-tasting, however, and is now in very good health.

Case VIII.—A. W——, Jr., age 30, tea-taster nine years; has been temperate and healthy; never experienced any effects from tea-tasting.

Case IX.—G. W. C——, age 35, tea-taster fifteen years; is strong and in good health; is temperate; uses tobacco; does not believe tea affects the flow of urine.

Case X.—W. T——, age 38, tea-taster seven years; healthy and temperate man; never experienced any effects from tea-tasting.

In all these cases the testimony was very strong as to the innocuousness of tea-tasting. It was the uniform opinion, also, from an extensive acquaintance with other persons in the trade, that the pursuit was a healthy one. The gentlemen whom I saw were all robust, well-looking men. They seemed, indeed, to be above the average of business men in many respects. There was a certain sallowness of skin among the older ones, which might, however, have been only a coincidence in livers. I heard of but one instance in which alcohol was ever used to excess, and in this case the excesses were rare and slight. Every one denied having dyspepsia, and one gentleman was, as stated above, even relieved of that disease after taking up the tea business.

With one exception, it was the uniformly stated opinion that Japan tea increased the flow of urine. Formosa tea was also said to do the same thing to a less extent. The other teas were thought to have no such effect.

In connection with this fact, it should be stated that Japan tea has of late years become by far the most popular variety, and more of it is imported than of all other kinds together. Green tea, on the other hand, is much less extensively used. This tea was stated to have no more effect upon the system of tea-tasters than black. I heard of two gentlemen who suffered from gravel, but they did not ascribe it to their tea-drinking.

The use of tobacco was quite universal, the tobacco being generally smoked. There is a difference of opinion as to whether the practice injures the taste.

Finally, it was admitted that tea-tasting, unless properly done, might prove injurious; if a person kept constantly swallowing large quantities of the hot infusion, he would experience bad effects. It was considered, very naturally, that the wisest plan was to taste tea without getting any more into the system than possible. If this plan were pursued with any reasonable judiciousness, no effects of any kind would be appreciated, even by a beginner, unless, of course, he had a certain natural susceptibility to the plant.

While I think that part of the rose-colored view of the business of tea-tasting is due to a certain *esprit du corps*, yet the evidence, even considering this, is very clear that tea-tasting, as carried on in this city, is as healthy as any branch of business—is, indeed, more healthy than some, such as that of dry-goods.

The question now is: How to reconcile this conclusion with the statements in regard to the toxic effects of tea? It seems to me that we can explain it in this way: the amount of tea actually taken into the system by tea-tasters is less than might be supposed, and the toxic effects of tea are less than would be inferred from some experiments and a good deal of current talk. A tea-broker takes into his mouth, approximately, an average of 0.70 c.c. (fl. ℥ xxi) of infusion of tea every day. This represents 8.26 grms. (gr. cxxix) of tea, which would contain, according to Roehleder, about 24 grm. (gr. iv) of *theïn*. This is a moderate dose of that drug every day. The drug, however, is taken at intervals, in small amounts, is a diuretic, and rapidly passes off. In addition, the volatile oil is to be considered; a great deal of this is inhaled, and it has, perhaps, a stimulant effect. It is taken in such small quantities, however, and passes off so rapidly, that one can readily understand why its effects are so inappreciable. Then there is a very insignificant amount of tannin taken—not more than that contained in the two or three cups of tea actually swallowed. Three gentlemen of whom I inquired had no constipation of the bowels.

Assuming, however, that I have made, as I think I have, a low estimate of the amount of tea gotten into the system, we must infer, since the system is not affected, that the active principles of an infusion of tea are very weak, and that large quantities are required to bring out their effects.

According to E. Peligot, there is from 2 to 4 per cent. of *theïn* in tea. G. J. Mulder makes it as low as .45 per cent. Assuming the amount to be 3 per cent., and that there are 2 grm. (gr. xxx.) of the leaf (a large estimate) in an ordinary cup, one would require to drink seven or eight cups in order to get a moderate dose (3 or 4 grm.) of *theïn*.

I am told that tea-tasters have sometimes drank fifteen or sixteen cups in succession, with a little bread, and have felt no effects. This may be due in part to their systems having become accustomed to the tea. It was uniformly stated, however, that no bad effects were felt when beginning in the business.

As regards the volatile oil, a great deal of this must be absorbed, although it constitutes but .5 per cent. of the tea. Tea-tasters get very much more of it proportionally than ordinary tea-drinkers. We must infer, then, since tea-tasters are healthy, that the volatile oil is a very weak agent.

It has been stated by Dr. Wolfe, of Glasgow, in a paper read before the British Medical Association last summer, that tea-drinking produces a bad effect upon the nutrition of the eyeball. This was shown by a softening of the vitreous humor, which became more or less filled with floating particles of pigment, these opacities finally seriously impairing vision. He had found the disease among all classes of persons, with nothing in common, so far as he could discover, except the habit of drinking large quantities of tea. Dr. Wolfe discovered also, that a larger number of cases of opacity of the vitreous humor occurred among the tea-drinking population of England and Scotland, than in France, Germany, and especially in Turkey, where tea is less used as a beverage. He admits that it is difficult to explain the *modus ope-*

randi in these cases, but considers it possible that the tannic acid, by precipitating the albuminoids of food, might impair digestion, lower the general tone of the system, and produce an irritation of the nutritive centres that might lead to various morbid changes, according to the predisposition of the person.

In the cases examined by myself, the eyesight was uniformly good, even in those who had tasted tea for years. Complaints of weak vision had not been noticed among their friends in the trade by those whom I questioned. It is very unlikely that Dr. Wolfe's theory has any basis in fact. Considering the immense consumption of tea, however, the subject is an important one, and further data should be collected.

I am aware that some of the calculations here given are only approximately correct. The facts at the bottom, however, are well established, and the conclusions are in accordance with practical experience.

At any rate, whatever theory be taken to explain the matter (and I believe the tea-tasters will think I do not credit them with tea enough), the fact that tea-tasting is a healthful pursuit seems to me to be indisputable.

MEDICINAL SPRING WATERS.

By JOHN C. PETERS, M.D.,

NEW YORK.

III.

In this article we will sift some of the pretensions of famous medicinal spring-waters. The Heilbrun, or *healing spring waters* of Bavaria, are regarded as powerfully alterative and tonic, and said to be useful in scrofula, strumous affections of the skin, rheumatism and gout, and for female complaints. The principal ingredients are 38 grains of table-salt and 6 grains of carbonate of soda in 16 ounces of water, $\frac{1}{4}$ grain of grain of iodide of soda and $\frac{1}{3}$ grain of bromide of soda, both in a latent state, with $\frac{1}{10}$ of a grain of carbonate of iron. If the same cheering and pleasant influences could be centred around two tumblers of water, with $\frac{1}{2}$ drachm of table-salt in it, and a pinch of carbonate of soda, doubtless all the cures which have been effected by these so-called wonderful waters could be accomplished at home, or in any pleasant country-place. The Aix-la-Chapelle waters have been celebrated since the time of Charlemagne. The four springs have from 18 to 20 grains each of table-salt in 16 ounces of water, 3 to 4 grains of carbonate of soda, 2 grains of sulphate of soda or Glauber salts, 1 grain of sulphate of potash, 1 grain of carbonate of lime, $\frac{3}{10}$ of a grain of bromide of soda, and $\frac{4}{10}$ of a grain of iodide of soda, both in a latent state, $\frac{1}{10}$ of a grain of carbonate of lithia, etc. Of course they are said to be good for cutaneous diseases, stiffness of the joints, paralysis, obstruction of the liver, and especially for syphilis.

Aix-les-Bains, in Savoy, is celebrated for rheumatism, gout, sciatica, and eczema. The principal ingredient is 1 grain of carbonate of lime in 16 ounces of water, and traces of a dozen other things, especially $\frac{1}{10}$ of a grain of fluoride of calcium and carbonate of strontia.

The Barrèges waters, in the Pyrenees, France, are used for inveterate chronic rheumatism and skin diseases; yet not one of its ingredients is present in the proportion of 1 grain in 16 ounces of water; it only has $\frac{3}{10}$ of a grain each of sulphuret and sulphate of soda, the same of table-salt, $\frac{1}{2}$ grain of silica or flint, $\frac{1}{3}$ of a grain of lime, and the same huge quantity of magnesia and soda.

Carlsbad, in Bohemia, is relied upon in obstinate constipation, affections of the liver, gout, and diabetes. The principal ingredient of the three springs is from 10 to exactly 19 grains of Glauber salts in 16 ounces of water; the next is from 8 to 9 grains of carbonate of soda; the third, precisely 8 grains of table-salt, 2 grains of carbonate of lime, and 1 grain of flint, in solution, 1 grain of fluoride of sodium and silicum, also $\frac{3}{10}$ of a grain of iron, $\frac{8}{10}$ of a grain of phosphate of alumina or clay. Yet many good Americans take long voyages and travels to these wonderful waters.

Ems, in Germany, said to be most useful in diseases of the mucous membranes and uterine derangements, especially in barrenness, sluggish liver, and irritative dyspepsia. The principal ingredient in all four springs is 14 or 15 grains of carbonate of soda in 16 ounces of water; the next, 7 grains of table-salt, then 1 grain each of bicarbonate of lime and magnesia, and finally $\frac{1}{10}$ of a grain each of baryta and strontia. That is about $\frac{1}{4}$ of a teaspoonful of soda in two tumblers of water and $\frac{1}{2}$ of a teaspoonful of table-salt.

Fachingen, near Ems, is said to be highly useful in diseases of the kidneys and bladder, and in acidity of the stomach. The principal ingredients are 28 grains of bicarbonate of soda in two tumblerfuls of water, 4 grains of table-salt, and 2 grains each of bicarbonate of lime and magnesia.

Franzensbad, in Bohemia, is gravely pronounced not only useful, but highly successful in all forms of abdominal plethora, and also in anæmia and chlorosis. Of course, the principal component in the five wonderfully different springs, is 17 to 26 grains of Glauber salts in each 16 ounces water, with 9 grains of table-salt, 1 grain each of carbonate of lime and magnesia, $\frac{3}{10}$ of a grain of iron, $\frac{1}{4}$ grain of carbonate of strontia, and a dozen other infinitesimal trifles. It is considered very important to remember that the springs, named after the Emperor Francis and the Empress Louisa, have from 5 to 7 grains of carbonate of soda in each two half-pint tumblers of the water.

The Friedrichshall Bitter water, in Saxony, is moderately active, alterative, and aperient, and considered useful generally in almost all diseases of the stomach, liver, and urinary organs. Epsom salts and Glauber salts are the great constituents, appearing in the quantity of 47 grains, or nearly a very small drachm of the former in each 16 ounces of water, and 40 grains of the latter, or from $2\frac{1}{2}$ to 3 grains in each ounce of the wonderful water; but then there are also 60 grains of table-salt, and 30 grains of muriate of magnesia and 10 grains of sulphate of lime in each two tumblerfuls of water, or little over $\frac{1}{2}$ grain in each ounce; but then $\frac{1}{4}$ of a grain of bromide of magnesia, in a latent state, in each pint of water, must not be forgotten.

The Gastein waters, in Austria, are decreed to be especially useful in nervous exhaustion, or neuroasthenia. It has 1 whole grain of Glauber salts in 16 ounces of water, and not a single other ingredient which comes up to that mark; but it has exactly $\frac{8}{10}$ of a grain each of table-salt and chloride of lime, $\frac{4}{10}$ of a grain of soda, and especially of the phosphate of alumina, with $\frac{1}{4}$ grain of carbonate of iron to each pint of water, with much smaller traces of fluoride of calcium and strontia.

The widely celebrated Homburg waters, one of which is called the Emperor's, or Imperial, others after Duke Ludwig and Duchess Elizabeth, have from 48 to 105 grains of table-salt in each pint of

water from 5 to 10 grains of carbonate of lime, 4 to 10 grains of muriate of magnesia—but the celebrated Steel or Iron spring has in addition 3/4 of a grain of carbonate of iron to each pint of water, while the others have only 1/4, or 1/2, or at the most 1/3 of a grain to each 16 ounces of water. We should not doubt, as the air of this place is found to be both pure and bracing, and everything that is pleasant and gay in life is furnished in this most fashionable place of resort, that the waters are especially good in hysteria and hypochondria—even in plethora, if one walks and dances enough—and in dyspepsia. They are also very, very slightly laxative, and very, very wonderfully tonic, without being overheating.

Kissingen has four mineral springs, the one supplying the *Kissinger Ritter*, which closely resembles Friedrichshall waters, in its proportions of Epsom and Glauber salts. But the principal ingredient of the other three is table-salt, of which the renowned Rakoczi water has 14 grains in each pint, then come 8 grains of carbonate of lime, and 4 grains of Epsom salts. These waters are said to give tone to the liver and kidneys, because they have about 1/2 grain of iron in each 16 ounces of water, and 2 whole grains each of chloride of potash and chloride of magnesium. It is also respectfully requested that the 1/2 grain of chloride of lithium in each two tumblerfuls be not forgotten. It is evident that it will take a great deal of these waters to produce a laxative effect, and how many gallons may be required to remove obstructions of the liver and morbid conditions of the kidneys we are unable to say; but very weak lime-water, with a little table-salt in it, aided by 4 entire grains of Epsom salts in each pint, and the whole complemented by the equally mild, dry, and salubrious climate which distinguishes this place, which is also justly said to be a pleasing and healthful place of residence, will accomplish all that the waters will.

(To be continued.)

A CASE OF
VALVULAR DISEASE OF THE HEART IN A CHILD,

Followed by Singular Motor Phenomena.

By TALBOT JONES, M.D.,

ST. PAUL, MINN.

Double valvular disease of the heart in children, congenital, and not depending for its causation upon acute rheumatism, is a sufficiently rare disease to possibly make interesting the brief report of a case which lately fell under my observation near this city. Some time during last winter, Mr. and Mrs. G., residing at Oakdale Station, distant some eight miles, brought to my office their child for examination. I found Lizzie G. a fragile little girl, with blue eyes and golden hair. She was four years old, and appeared to have been delicate from her birth. The father, a well-to-do farmer, was the picture of health; the mother, too, enjoyed fair health, though of rather a delicate appearance. Their object in seeking medical advice was to ascertain the present condition of their child, and learn what complaint it was now laboring under. Questioning them, I learned that the child had occasional attacks of dyspnœa, especially after some unusual exertion; at such times having more or less palpitation of the heart, was restless, uneasy, had a dry cough, sometimes had difficulty of breathing, coupled with stoop, often awakening in great alarm, owing to some frightful dream. Occasional epistaxis. There was no history of former rheumatism or scarlet fever. Neither father nor mother had ever suffered from heart disease. The child's face was pale and her lips bloodless; she was anæmic, and the number of respirations were increased. Physical examination revealed the apex-beat of the heart in the sixth intercostal space, and displaced laterally and to the left. Impulse strong and heart beating tumultuously. With the stethoscope properly placed, endocardial murmurs were heard, but the heart's action was so rapid and violent that it was quite impossible to determine the seat of the lesions. Administering digitalis, to slow and quiet the heart's action, I made the second examination some six or eight hours later.

The lesions could not be located, there were present two distinct murmurs. Just over the apex, and transmitted laterally toward the lower angle of the scapula, a loud murmur could be heard with each ventricular systole—a mitral regurgitant murmur. In addition to this, and also over the apex, but limited to this location, there was a presystolic murmur heard, which was abruptly arrested with the first sound of the heart—a mitral obstructive murmur. Lungs perfectly normal. I gave the parents a very unfavorable prognosis, remarking that the chances were greatly against the child reaching maturity. I prescribed a tonic of iron and strychnia; gave directions with regard to diet, exercise, and cautioned the parents against allowing our little patient to become excited, or to exert herself too violently.

I did not see the case again for some two or three months, when, one day, I was summoned out, in great haste, and found the child in a paroxysm of dyspnœa and almost cyanotic. This attack was brought on by over-exertion, and a neglect to continue the treatment I had advised. I remained till the child recovered from the attack, and again left directions for subsequent treatment. This was the last I saw of the little girl for about five months. In the meantime the case had almost fallen out of my mind. I was ignorant whether the child was better, had fallen under the charge of some other physician, or was dead.

However, at midnight, on October 10th, I was again hastily summoned to see our little patient. The messenger declared the child was in a desperate condition, and urged me to lose no time in reaching the bedside. I found his fears only too well grounded: a mere glance showed me that the child was moribund. Questioning the parents about the present paroxysm, I ascertained that the child had greatly improved in general health since I last saw her. The attacks of giddiness and palpitation did not occur nearly so often as formerly; her appetite was fair, and her health in every way improved. This last attack was due to the child having unduly exerted herself while at play the day before. She was suddenly attacked with violent palpitation; experienced great cardiac oppression; was giddy; and soon became cyanotic, and was in this condition when I reached her at night.

Upon examination I found the heart was beating very rapidly and irregularly, though its impulse was not nearly so strong as when I examined it five months before. This led me to believe that the former predominant hypertrophy was now, in turn, succeeded by dilatation. The true explanation of the weakened impulse, however, may have been that there was fluid present in the pericardium, as a result of pericarditis. Another factor may have been the

weakness due to approaching dissolution. The child's face was pale and bathed in perspiration. There was no œdema or dropsy present, nor had there been at any time. With the ear over the præcordia the same murmurs were heard which had originally given rise to the unfavorable prognosis. The breathing was rapid, and the child in a comatose state. There was the normal vesicular resonance on percussion over the lungs, but the area of præcordial dulness was increased, extending downward below the sixth rib, and laterally considerably beyond the normal location. This fact, taken in connection with the fever present, as well as the previous history of the case, led me to believe that I now had to deal with endo- and pericarditis as a complication of the valvular disease. I must say, however, that after a careful search for a friction or rubbing "to-and-fro" sound, I failed to discover one. The most interesting and singular symptom observed in this case was the convulsive twitchings of the right side of the body and face, which movements recurred at intervals of some three or four seconds. These convulsive movements of the side were quite strong—the leg being drawn up with considerable force. At the same time the arm, especially at the elbow, was raised from the bed. Coincident with this, the muscles of the face, on the corresponding side of the body, were drawn in violent and fitful contractions, resembling the twitchings which would be produced by a galvanic current. Death took place an hour or two later.

Little, of course, could be done by way of treatment. The tincture of digitalis was given, but the heart would not respond to the remedy. Counter-irritation over the precordia was employed, and this constituted the treatment. An autopsy was not granted. I have been led to record this case chiefly on account of the singular phenomena observed in connection with the unilateral twitching of the body, which was so marked a feature in the case. A satisfactory explanation for this has not yet occurred to me. The practical question is what caused these convulsive movements of the right side of the body, in this, a case of valvular disease of the heart? Was it due to some regurgitation or fibrinous concretion having been swept off the mitral valve, carried thence as an embolus to the motor tract of the brain, and there gave rise to these unilateral twitchings? It will be objected that embolism, just as apoplexy, gives rise to paralysis and not exaggeration of motion. In the vast majority of cases this is true, but it is equally true, as Dr. Hughlings Jackson has fairly shown, that chorea minor is occasionally the result of embolism of a cerebral vessel supplying the corpus striatum and neighboring convolutions. Now, if embolism can give rise to the exaggerated motor disturbances of chorea, why may it not be a rational explanation of the exaggerated motor disturbances observed in this case of heart disease. The proneness of embolism to occur in cases of valvular disease of the heart, it will only be necessary to mention.

Again, some one may suggest, as a satisfactory explanation of these remarkable phenomena, that the movements in question were dependent upon metastatic inflammation in the brain due to an embolic plug. But the fatal objection to this explanation is that, granting that localized inflammation of the brain may give rise to motor disturbances of the body, still in this case the onset was too sudden, and the interval between the first manifestation of these twitchings and the fatal close was too brief, for it to be chargeable to localized inflammation in the brain. If the motor disturbances observed were due to ordinary convulsions, which in children precede death in such a variety of diseases, the case, for this fact, is by no means robbed of its interest. The question is still a pertinent one: Why did the convulsions affect but one side of the body? Again, are not infantile convulsions, as a rule, bilateral, and not, as in this case, unilateral.

The mode of the seizures, together with the previous history of the case, fully justified me in excluding reflex causes due to peripheral irritation, such, for example, as worms, teething, constipation, etc. Assuming, then, that the cause was central, the question arises, will ordinary infantile convulsions explain the motor phenomena observed in the case?

Convulsions in children, in the great majority of cases, continue from a few minutes to an hour or two—rarely longer than four hours. With these facts in view, I think a physician would be almost reckless of his opinion who would give it as his belief that the motor disturbances were due to ordinary infantile convulsions. Finally, when we again ask the explanation of the exaggerated unilateral movements, it but brings us back to our original starting-point.

We have given several possible explanations only to expose their error.

The true cause is with certainty not known, though I feel that that which supposes them due to embolism of one of the vessels supplying the motor centres of the brain, offers the most reasonable explanation of the motor phenomena in this, a case of valvular disease of the heart.

LUGOL'S SOLUTION AND TANNIC ACID:

A Local Application in Diphtheria.

By D. McFALLS, M.D.,

PARK CITY, UTAH.

As diphtheria is now prevailing to a fearful extent in many localities throughout this country and in Europe, it seems to me that the discovery or the use of any means, either local or general, that afford relief in this grave disease, ought at once, or as soon as those remedies are sufficiently tested, be made known to the profession.

I have had an extensive experience in the treatment of diphtheria in both hospital and private practice since 1860, and have employed the various gargles and washes recommended by different authors and practitioners of medicine, including steaming, with varying results; but more recently I have made use of Lugol's solution, thickened with tannic acid to the consistence of thin cream, with better effects than any of the others heretofore in use. This mixture should be employed early in the disease, when the coating first makes its appearance. The tonsils, on which the exudation is usually first seen, should be well painted over, using for this purpose a large-sized camel's-hair brush, or a swab made of old linen. If this medicine is used at this time, even when the tonsils are considerably swollen and much inflamed, I have seen it often prevent the formation of the coating, and thus the disease has been apparently cut short or aborted. When the patient is not seen until the coating is quite extensive over one or both tonsils, or the back part of the throat, as is too often the case, the mixture should still be applied, not only over the exudation, but the parts adjacent to it

should be painted over as far as can be reached without difficulty.

Soon after the application of this mixture the coating will be seen to have contracted or wrinkled, and will come away without bleeding, leaving the parts quite healthy, and without those deep, irritable ulcers that are almost invariably seen when the coating is allowed to remain until suppuration has taken place. Not only this, but the swelling of the tonsils and the glandular enlargements about the neck will be diminished.

I first commenced the use of this mixture by noticing its beneficial effects in tonsillitis and in erysipelas, as well as in some other local inflammations. Still, notwithstanding the benefits derived from the use of this remedy, I do not rely entirely upon this or any other local treatment for the cure of the disease. If the disease is local at the beginning, according to Oertel, then this local treatment, early employed, is certainly indicated; for there are no remedies yet discovered, I believe, that will destroy those microcci which are said to be the cause of this disease, or prevent their rapid reproduction, when brought into immediate contact with them, as iodine and tannic acid. If, on the other hand, the disease is at first constitutional, as is claimed by many, and the throat difficulty is only a local expression of the general disease, then any means or remedies that will control the amount and spread of this exudation into the trachea and air-passages will be, to a very great extent, beneficial. The frequency of the application of this remedy depends entirely upon circumstances and in what stage of the disease the patient is first seen. If the coating in the throat has become very thick and firm, the mixture should be applied *three* or more times in the twenty-four hours; and whenever any new patches of coating appears, these patches should be touched as soon as they show themselves. Should the throat become sore, and deglutition is attended with pain, then a solution of carbolic acid may be applied with benefit—more, however, as a local anæsthetic than for any other purpose.

I have been in the habit of using cold compresses externally for the first three or four days. A cloth should be folded five or six thicknesses, of sufficient length to reach from one ear to the other; this should be wrung out of cold water and applied; over this a handkerchief tied upon the top of the head. In severe cases this should be changed every ten or fifteen minutes, or as often as it gets warm.

As to constitutional treatment, tincture of ferrichlorate of potassa, quinine, and stimulants are principally relied upon. I use a strong solution of chlorate of potassium and the tincture of iron, mixed together in simple syrup. Of this, in severe cases, a teaspoonful is given every half-hour, and every hour in more moderate cases; the quinine every four hours, and the whiskey in liberal quantities. Emetics and cathartics should not be given, even at the commencement of the disease. I have used steaming *most thoroughly*, as recommended by Oertel, both before and after the membrane had extended into the trachea, but with no benefit. I have saved quite a number of patients, after the croupal cough came on, by the use of zinc emetics, and by keeping them alive, as it were, until the coating became detached and was coughed up. When the dyspnœa is very great and returns at intervals, much relief may be given by the use of bromide of potassium. I have no confidence in tracheotomy in this disease. Those who recover after the operation would undoubtedly have lived if the operation had not been performed.

Reports of Hospitals.

THE PENNSYLVANIA HOSPITAL, PHILADELPHIA.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

(Reported for THE MEDICAL RECORD.)

TYPHOID FEVER COMPLICATED BY SWELLING OF THE PAROTID GLAND.

THE case was one of typhoid fever, unmarked, at first, by any peculiarity, except that the attack had been one of unusual severity. The temperature was as high as 105 at times, and there had been a great deal of muttering delirium. There had also been a little more diarrhœa than is customary.

On December 28, 1879, convalescence had set in, the temperature being 99°. On January 1st the temperature was still lower, the thermometer in the axilla marking only 97½°. The diet was increased, and the diarrhœa began to be replaced by constipation. This constipation was so marked that the bowels had to be evacuated by means of a cathartic.

On January 11, 1880, with but slight increase of temperature, the patient began to complain of stiffness, swelling, and pain at the angle of the left lower jaw. This stiffness and swelling increased in spite of the free local application of iodine. Thirty-six hours after the swelling was first noticed the patient's temperature began to show an inclination to rise. 100° was reached, but the fever stopped there and again ran down, until, on January 16th, it was the same as the record of the first convalescence showed. On January 17th it was 98°.

For a few days after January 11th the swelling persisted; there seemed to be less stiffness and pain, but this improvement was only temporary, for on the 17th it again increased. This stiffness was accompanied by hardness and swelling, not only of the parotid gland, but also of the surrounding tissue. The tension extended all over the cheek; the patient could not open his mouth or swallow without pain.

The glands lower down in the neck, and the submaxillary gland, were not affected.

In considering the case, attention was called to the very great rarity of this complication of typhoid fever, emphasis being laid on the fact that Trousseau and Chomal had each only recorded *one*, Murchison in his enormous experience of typhoid fever only *six*, and Da Costa only *three* cases.

It was thought that the presence of parotid swelling, as a complication of enteric fever, suggested several questions: How such a complication arises, what it means; how it modifies the prognosis, how it should be treated.

Before proceeding to discuss these points it was stated that parotid swelling was quite a frequent complication of typhus fever; that in the typhus fever epidemic of 1870 at least four of the cases of typhus in the wards of the hospital had parotid swelling.

It was thought that the complication did not differ materially as occurring in typhus and typhoid fever, but that the tendency of the swollen parotid to suppurate was greater in typhoid fever.

With regard to the stage of typhoid fever at which this complication arises, the belief was expressed that it was generally when convalescence has set in.

It was considered a dangerous complication, although it was allowed that there was a curious diversity of opinion with regard to this point among clinicians, some believing it to be a favorable, and others an unfavorable phenomenon.

The opinion that it is an unfavorable complication was based upon the danger of death: (1) from pressure upon the trachea; (2) from the discharge of pus into the air-passages; (3) from general septic poisoning.

It was believed that the swelling of the parotid was an indication of the profound blood-poison. As it occurs after convalescence has set in, it was thought to show that the poison was still in the system, and that it had located itself in the parotid gland.

Unless an early incision is practised, it was further shown that there was danger of purulent infection. The swelling may subside slowly, or it may persist, and when it thus persists it shows that the impression made upon the system by the blood-poisoning has been very profound.

The following treatment was pursued. The spot was painted with iodine, but as no good seemed to come of this treatment, ice was applied steadily in bladders. This was found to relieve the tension, heat, and swelling, so that for a few days it seemed as if the swelling had entirely yielded to the ice; but it soon returned. It was determined to still apply the ice steadily, and thus to try and prevent the occurrence of suppuration; but, if suppuration took place in spite of the ice, it was thought that the ice-bag should be at once removed, and that suppuration should be favored by the application of a poultice, and that the pus should be let out by an early incision. It was thought that a blister might be applied with advantage after the ice had been persevered in for several days.

The medicinal treatment employed consisted in the administration of gtt. xx. of the tincture of the chloride of iron every three hours, together with gr. xij. of quinia and f. ʒiv. of whiskey each day.

It was thought that at a later stage some alterative, such as the iodide of potassium or Lugol's solution, given internally, would be of advantage.

SOME POINTS OF INTEREST WITH REGARD TO THE COMPLICATIONS OF ACUTE ERYSIPELAS.

Some years ago an eminent French observer made the statement that endocarditis is the rule in erysipelas, and based his opinion upon the fact that a cardiac murmur is always present in the disease. These observations have been repeated at the Pennsylvania Hospital, and it has been conclusively shown that endocarditis in erysipelas is wholly exceptional, and bears no such relation, in point of frequency, as the French observer concluded. In the larger proportion of cases of erysipelas at the Pennsylvania Hospital, as the disease is declining, or it may be just at the height of the attack, a short, soft systolic murmur, which is not the result of an endocarditis, but is just such a blood-murmur as is met with in typhoid fever, has been found to be present; but this is a passing murmur, is unaccompanied by any signs of a disordered circulation, and never continues after convalescence is established.

With regard to the presence of albumen in the urine, investigations made at the same hospital some years ago demonstrated conclusively that, in all cases of erysipelas of any severity, albumen is present in the urine, and that its presence is a phenomenon which belongs to the disease. It has also been proven that the albumen is generally to be found in the urine when the disease is at its height. This albuminuria is not, as a rule, associated with epithelial casts, since they are few and scanty.

These observations have further shown that the following valuable prognostic indications can be obtained from the presence of albumen in the urine in this disease, and from its amount: (1) When albumen appears in the urine, it may be taken for granted that the morbid process has reached its height; (2) when the amount of albumen in the urine is large, the attack is likely to be graver and more protracted, and a relapse is more likely to happen; (3) the presence of albumen in the urine teaches the physician to look out for the kidneys in the course of the disease, for if they are allowed to become clogged, impurity of blood may be added to the erysipelatous inflammation.

BELLADONNA IN CONSTIPATION.

Very good results have been obtained in cases of obstinate constipation by the administration of f. ʒ j. of sweet oil at bedtime, and gtt. i. of the fluid extract of belladonna, thrice daily after meals, in f. ʒ j. of Huxham's tincture.

Progress of Medical Science.

IMPULSE OF HEART IN ANÆSTHESIA.—The following are the conclusions of Dr. John W. Corson in a paper read before the Essex County Medical Society, New Jersey, April, 1879, entitled "Impulse of the Heart in Anæsthesia."

1. Where structural changes of the heart are clearly evident, *chloroform should never be used.*

2. In the "more favorable class," *ether alone may* be gradually and very *cautiously* administered.

3. Where there is fear of "*sudden death*," either from "aortic regurgitation," so liable to this, or from that obscure disease, "fatty heart," *no anæsthetic should be used.*

4. Whenever, either in organic changes or "functional affections" of the heart, the *impulse* has been decidedly *weakened*, only *ether* should be *sparingly* administered.

5. Statistics are noted, showing in round numbers the deaths from chloroform to be about one to three thousand administrations, and those from ether to be one in twenty-four thousand; or eight from chloroform to one from ether.

The "inhaler" of Dr. Allis is strongly commended. It is convenient for chloroform, and especially useful in making ether more pleasant and *manageable.*

6. *The impulse of the heart* can be most conveniently *tested* delicately by the *ear.* The patient should be placed in a sitting position, but leaning a little forward, so as to let the apex strike well against the ribs, while the chest inclines over the head of the physician. We thus feel the impulse, and catch the "first" sound at the same moment.

If the impulse seems weak, it can be made more distinct by asking the patient to walk hurriedly round the room or up a pair of stairs, and then listen quickly after. We thus also bring out the faintest valvular murmur, if any exists. With any "suspected heart," it is always best, before using chloroform or ether, to further test its strength by these two questions, asked very quietly. 1. On hurrying a little up a second pair of stairs, is there actual distress? 2. Is the patient subject to fainting readily?

7. The writer urges the most ample preparations for *every case of anæsthesia*. All known safeguards should be adopted. The best position for the physician who administers is *sitting on a chair*, close to the head of the patient lying beside him, with the fingers of the left hand on the pulse at the wrist, with his eye watching the heaving chest and livid face, while the fingers of the right hand are free *to test* the sensitive conjunctiva.

The ventilation should be perfect. In addition to other openings, a piece of muslin, *ten inches wide*, can be tacked inside a lower windowsash, raised *six inches*, to send a current of air to the ceiling, to be warmed before using, and to *sweep away* the impure *cloud of chloroform or ether above*.

There should be the usual four hours of fasting previously from *usual food*. In cold weather, extra socks and drawers are needed, and the temperature of the room should not fall below sixty-five degrees. With the very nervous or feeble, it is a useful preparation to give an ounce of brandy or whiskey in water.

Of the greatest importance, for safety, is the horizontal position. We should ever be ready to use Nélaton's brilliant device of hanging the head *very low*, in case of *danger*. Two implements to save should be lying ready for use. These are a pair of artery forceps, or a hook, to pull forward the tongue in case of *deep stertorous breathing;* and a faradic battery, to rouse the failing heart, in case of need. We should also be prepared, in emergency, to use artificial respiration. The writer is in favor of the *gradual administration* both of ether and chloroform. *Where there is so much at stake, it is better to err on the side of caution.*

Tubercular Leprosy.—An interesting case of tubercular leprosy is reported by Dr. Hyde, Professor of Dermatology at the Rush Medical College. The patient is a native of Sweden, forty-three years of age. There is no evidence that any of his ancestors suffered from the disease, but two of his brothers died from a similar affection, and the account given of his little daughter (who was left at home in Nebraska, and did not come under the personal observation of Dr. Hyde) makes it probable that she is also suffering from the same affection. If this supposition is correct, it is the first recorded case of inherited leprosy occurring in the United States. The patient was given internally an emulsion of chaulmoogra oil, and an ointment of one part of oil to four of lard was applied externally. This oil is obtained by expression from the leaves of the gynocardia odorata, and, according to Dr. Wyndham Cottle, can be given in doses of five minims, gradually increased daily. It has lately been recommended very highly in the treatment of leprosy, although some observers have failed to obtain from it satisfactory results. One month after the commencement of treatment, the patient wrote that he was feeling a great deal better, his voice was becoming clearer, the tubercles decreasing in size, and the normal sensitiveness returning to the lower extremities. He further stated that his daughter, who is taking the oil in one-minim doses, and using external inunction, exhibits an equally marked improvement, the tubercles diminishing in size upon her extremities.—*The Chicago Medical Journal and Examiner*, December, 1879.

Stroma of the Red Globules.—In the course of his studies on the evolution of the red globules, M. Hayem noticed that when a thin layer of dried blood on a glass slide is treated with distilled water, the water does not dissolve the globules, but simply withdraws from them the hemoglobin. He has recently made use of this fact to study the nature of that part of the globule to which German authors have given the name of the *stroma*. He spread thin layers of blood on glass slides, let them dry in the open air, and on examining them with the microscope found the red globules arranged in rouleaux as in humid preparations. The diameter of the elements was measured, and a stream of distilled water was then made to flow gently over each preparation. The water extracted the hemoglobin, while the decolorized globules remained attached to the glass and retained their arrangement in rouleaux. The distilled water was then replaced by an iodized solution, and it was found that none of the marked globules had disappeared. They were reduced to a delicate pellicle, tinged yellow by the iodine, and bounded by a double contour. By measuring the elements before they were detached from the glass, he ascertained that they had preserved very exactly their original dimensions. There was nothing left of the red globules but this delicate envelope; even with the highest powers no detail of structure could be discovered, neither filaments, nor granulations, nor nucleus. This method of preparation, which succeeds as well with the blood of animals, either viviparous or oviparous, as with human blood, demonstrates, according to M. Hayem, that the assumed stroma of the globule is only a delicate pellicle of proteic matter, insoluble in water, which evidently forms the external layer of the globule, since its dimensions are the same as those of the colored corpuscle.

In these preparations of dried blood, the hematoblasts, whenever they were fixed to the glass without alteration, acted like the red corpuscles, presenting the same persistent, exterior pellicle. Instead of the iodized solution, the alcoholic solution of rosaniline or of eosine can be employed as a coloring reagent. *Gazette Médicale de Paris*, November 1, 1879.

Two Cases of Extirpation of the Kidney.—Prof. Czerny, of Heidelberg, reports two cases of extirpation of the kidney, of which one terminated favorably. The first case was one of cancer of the kidney, the tumor filling the entire left half of the abdomen. The operation was undertaken at the request of the patient, after its dangers had been fully explained to him. The incision was made in the linea alba, and the mesocolon descendens was divided over the tumor. As the operation proceeded, it was found that the cancerous mass had perforated the capsule and the inner layer of the mesocolon. The hemorrhage was very profuse, and could only be controlled by compression of the aorta; it finally became necessary to ligate the aorta. The patient died ten hours after the operation. The second case was one of pyonephrosis, with fistulous opening under the eleventh rib. When the discharge from the fistula was free, the urine passed by the patient was clear; but when the fistula ceased discharging, the urine was thickly loaded with pus, and was passed with severe pain. In this case the extra-peritoneal operation was chosen; the incision being made along the anterior border of the quadratus lumborum, and involving the sinus. To obtain more room, 9 cm. of the eleventh rib were resected subperiosteally. The entire hand could then be passed into the wound, and the kidney, which was enlarged to three times its usual size, was easily separated and drawn out. The pedicle was secured with silk and elastic ligatures, and the kidney was cut off at the hilus. The wound was

washed out with a five per cent. solution of chloride of zinc, and tamponed with thymol gauze, and the external incision, which was about 20 ctms. in length, was then closed with sutures to about half its extent. The patient did remarkably well after the operation; she had very little fever during the entire course of her convalescence. The ligatures with the necrotic pedicle came away on the twenty-third day, and two days afterward the patient was out of bed. Two weeks later she left the hospital, and it is stated that she has since become pregnant.

Prof. Czerny believes that both methods of nephrotomy, the extra-peritoneal and the intra-peritoneal, are legitimate, but that the latter is, *ceteris paribus*, the less dangerous. Hence, when the kidney is fixed, and is not too large, lumbar nephrotomy is to be preferred. For movable kidneys, however, laparotomy must be performed.—*Centralblatt fur Chirurgie*, No. 45, 1879.

The Lactosuria of Puerperal Women.—Investigations recently carried on in the chemical laboratory of Prof. Hoppe-Seyler, in Strassburg, have confirmed the observations of Hofmeister, who found in the urine of puerperal women a substance possessing all the characters of milk-sugar. In addition to the other reactions, when the crystals of this substance were gently heated with nitric acid, mucic acid was obtained; this reaction is alone sufficient to prove its identity with milk-sugar. The investigations showed further, that the quantity of milk-sugar in the urine increased in direct ratio to the engorgement of the breasts with milk. Whenever the tension in the milk-ducts was greater than that in the surrounding lymphatics, those parts of the milk that are capable of diffusion and transfusion, viz., the water, the milk-sugar, and the salts, were taken up by the blood; hence we have to deal here with a resorption-diabetes. The quantity of the milk-sugar in the urine was very great when the child was not put to the breast.—*Centralblatt fur Chirurgie*, Nov. 8, 1879.

Transmission of Hydrophobia from Man to Rabbits.—M. Raynaud inoculated a number of rabbits with the saliva and blood of a hydrophobic patient on the day before death. The inoculations of blood gave negative results; the inoculations of saliva, however, were followed by rabies in a relatively short space of time, at most a few days. M. Raynaud also extirpated the submaxillary glands of two rabid rabbits and inoculated them on two healthy rabbits; the results were equally positive, that is to say, the inoculations were followed in a short time by the symptoms of rabies. No reliable case of the transmission of rabies from man to man has yet been recorded, but M. Raynaud thinks that after his demonstrations of the possibility of its transmission from man to rabbits, it is fair to conclude that the results would be identical in the case of man, if accidentally inoculated.—*Le Progrès Médical*, Nov. 15, 1879.

On the Immobilization of Diseased Joints.—At the meeting of the *Société de Chirurgie*, on November 12th, a paper on Ankylophobia, by M. Verneuil, came up for discussion. In that paper M. Verneuil stated that inflamed joints regain their power of movement more rapidly when they are kept immovable for a very long time. M. Tillaux contested this statement, and claimed that too prolonged immobilization may lead to unpleasant results. He formulated his theory of the treatment of arthritis on the following propositions: 1. As long as an acute or chronic arthritis is still in the inflammatory stage, the only rational treatment is absolute immobility; 2. If, however, the joint be in a bad position, it is necessary to correct this before immobilizing the joint; 3. When the inflammation has entirely ceased, and any stiffness remains, the joint must be made flexible by artificial movements; 4. If the inflammation be chronic, if the case be one of white swelling, and the position of the limb be good, artificial movements should not be practised.

M. Championnière also took issue with M. Verneuil. He claimed that prolonged immobilization is liable to be followed by retractions, rigidity, and functional impotence, which in the case of some fractures, as of the olecranon and patella, are regarded by many authors as more objectionable than fibrous union. He cited a case in which, after an apparatus had been worn for two months for a fracture of the radius, there was considerable rigidity of the fingers, wrist, elbow, and shoulder. He added, that in some forms of suppurative arthritis, mobilization had seemed to him exceedingly valuable. His experience only covered five cases; but in two of them, in which the knee-joint had been freely opened for the evacuation of pus, he had practised artificial movement of the joint from the very first day, and at the end of a month the movements were much freer than in a case operated on by M. Verneuil for foreign body in the knee, and treated by immobilization. These two patients were almost able to touch the buttock with the heel. In the other cases the joints were kept immovable for a time, and the movements were less perfect, or at least were regained less rapidly.

M. Terrier stated that Jarjavay only kept fractures of the radius in an immovable apparatus for about twelve days, for fear of consecutive articular rigidity, and that his results seemed to be good.—*Le Progrès Medical*, Nov. 15, 1879.

On Hydrophobia.—After numerous observations and experiments, Gattier has found that the saliva collected from a living rabid dog retains its poisonous powers when dissolved in water, for from twelve to twenty-four hours. This fact is important, inasmuch as it shows that the vessels from which a rabid dog has drunk should not be used for at least twenty-four hours afterward, and also renders it probable that the disease has sometimes been communicated simply by the use of such vessels, and without direct infection by a bite. He has also found that the cadaver of a mad dog does not lose its infecting power as soon as it becomes cold, but that it retains this power for twenty-four hours; this fact should be borne in mind during the examination of the mouth and neck of the dead animal.

In respect to the mooted question of the transmissibility of rabies from dogs to rabbits, Gattier has attained positive results, and he has also succeeded in transmitting it from rabbit to rabbit. In these animals the principal symptoms were paralysis and convulsions. The disease proved fatal in from four hours to four days, reckoning from the outbreak of the symptoms. The duration of the period of incubation in rabbits was shorter than in other animals, a fact which renders the former peculiarly suitable for experiment. Subcutaneous injections of salicylic acid, employed with a view to prevent the outbreak of the disease, proved utterly useless.—*Allg. Med. Cent. Zeit.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 24, 1880.

SURGEONS IN PUBLIC JOURNALS.

Those of our readers who may peruse the generous and manly defence of Mr. Keith by Dr. Marion Sims, may be ready at first blush to take us to serious task for our remarks concerning the reports of operations in public journals. If, by anything we have said, we conveyed the impression that Mr. Keith was not entitled to the reputation of a remarkably successful surgeon, and was not worthy of all praise for splendid achievements in ovariotomy, we have certainly been misunderstood. We perfectly agree with our correspondent in his estimate of the subject of his epistle. So firm is our belief on this point, that we admit from the start all the good that can be said of him.

Our remarks concerning the notice of operations in public journals were made from a general standpoint. It is just such cases as that of Mr. Keith which establish precedents for all sorts of laudatory notices, and open wide the door for any amount of medical advertising. It is hardly the question whether or no a particular surgeon deserves the reputation of a brilliant and successful operator, but whether the profession as a body is benefited by such notices as from time to time find their way into the daily papers. It appears unjust on its face to deny any great man the benefit of a reputation which he may have gained; but, in view of the fact that just estimates of real worth are not usually made by newspaper reporters, the profession thinks it better to allow the really worthy to suffer, rather than the unworthy should profit at their expense. Where one good man gets his meed of praise and strict justice in the daily press, a hundred are apt to be gratuitously advertised on the flimsiest possible pretext. It is just this latter class that benefit by such proceedings, and it is on this account that the profession, as a body, has been led to protest against newspaper notices altogether. It has not yet been settled where the line shall be drawn between the deserving and the undeserving, and it never can be until the public is educated to the point of being able of itself to discriminate between the two. At present the newspaper reporter will make as much of the surgical attendant who removes a wen or extirpates a fatty tumor, as of the operator who successfully excises the spleen or takes away a kidney.

In Scotland, the public may be sufficiently educated to appreciate a great and good man, but in this country the case is altogether different. If our people possessed the right standard of intelligence, how many of the really great men in our profession would be known to the world, and how few of the present pretenders would be heard from! Humanity could then rejoice understandingly, and the profession could be properly appreciated and appropriately honored by the world at large.

We cannot help believing that our esteemed correspondent allows his enthusiasm to get the better of his judgment, when he virtually charges the profession of this country with narrow mindedness in objecting to public notices of medical men. There is no narrow-mindedness in any policy which contemplates justice to the greatest number. It is so much the exception for the deserving medical men to get noticed by the press, and so common for such as are hardly second-rate to have a newspaper notoriety, that the true dignity of the profession appears to be best preserved by a modest silence.

It is not on general principles considered fair for one man, or any set of men, to benefit themselves at the expense of their equally deserving brethren. There is something else for the larger fish to do than to swallow up the smaller ones. If in this country, as in Scotland, the men really entitled to the distinction would always be in front, the profession could afford to be liberal in the sense claimed by our correspondent, and to take a just and noble pride in its true representatives. As it is, however, the time has not yet come, in this country at least, when humanity at large can have an opportunity for rejoicing in finding such men. We have no doubt there are many such here, but we have yet to hear of them through the newspapers.

NEW WARRANT FOR THE BRITISH ARMY MEDICAL DEPARTMENT.

The new warrant, or code of regulations for the medical department of the British army, has at length appeared, and seems to excite very general approval. The only serious criticism made is upon the fact that but half the officers are to be appointed by competitive examination, the other half being at the dictation of the Secretary of War.

The British army surgeons have different grades from those of our army, and the position and pay of these officers is scarcely as good. The first position assigned the appointed medical officer is that of sur-

geon on probation, at $2 a day. He is then obliged to pass through a course of study at the Army Medical School, at the end of which is a competitive examination. Should he pass this, he becomes a surgeon on $1,000 a year, which in five years is increased to $1,250. Having served twelve years at full pay as surgeon, he may be promoted to surgeon-major at the lucrative salary of $1,800 a year. This, after fifteen years of service, is increased to the amount of fifty cents a day.

A person may be surgeon-major all his life, unless he has the good fortune to be selected for promotion to brigade-surgeon. The chances are smaller yet that he ever rises still higher and becomes deputy-surgeon-general, or surgeon-general. The rank of the medical officers is as follows: The surgeon-general ranks as major-general; deputy surgeon-general, as colonel; brigade-surgeon and surgeon-major after twenty years' service, as lieutenant-colonel; surgeon-major of less than twenty years' service, as major; surgeon, as captain; surgeon on probation, as lieutenant.

An excellent feature, which to some extent offsets the very low rates of pay, is that of giving gratuities in case of retirement. Thus, after ten years' service, an officer may retire with a gratuity of £1,250. This amount is increased with the length of the service.

The effect of these new regulations has already been very marked. Eighty students have entered for the coming competitive examinations. Before the warrant, it was with the greatest difficulty that any good men could be secured for the service.

VOCAL PHYSIOLOGY.

It is said that one of the leading sopranos of this city is making some study of the physiology of the voice, and has already furnished contributions to that department of science. We believe it is a fact that in the history of music and musicians there have been only two persons who have contributed any scientific knowledge concerning the organ which has been the source to them of so much revenue, reputation, and pleasure. Manuel Garcia, the brother of Mlle. Malibran, and now a famous teacher in London, first discovered that the vocal cords could be seen and studied in the living subject. Mrs. Emma Seiler subsequently discovered certain cartilages in the vocal cords which she believes are essential in the production of falsetto notes. These cartilages had not been noticed by anatomists previously, because, as stated, they exist only in woman, whose larynx being smaller, is not often dissected minutely. Mrs. Seiler is now conducting a successful school of music in Philadelphia.

It is not long ago that the idea of a knowledge of vocal physiology being necessary to a singer or speaker would be uniformly ridiculed; and there is no doubt that the most famous artists have achieved success by empirical help alone. The fine arts have always been far in advance of the classified knowledge of those laws which are ultimately discovered to be at the base of them. To the artistic temperament, also, scientific facts and methods are generally distasteful. It is felt that a high note can be sustained just as well without a knowledge that the crico-thyroidei are in a state of firm contraction.

Such reasoning, however, seems to be somewhat narrow. For, after all, it is only few, comparatively, who by empirical methods can be successful, either as teachers or pupils, and those few must have a great natural talent. The number of persons who use the voice has been vastly increased in late years, and with them, necessarily, the number of instructors. The scientific knowledge already acquired in regard to the production and care of the voice is so definite that no intelligent teacher can err in the fundamental facts he has to impart. The studies of Garcia have saved thousands of voices. The theories of Mrs. Seiler, that with each register there is a marked change in the anatomical arrangement of the organs that are concerned in producing the voice, have certainly great importance.

But, whatever be the facts as to the propriety of singers and speakers being fortified in their artistic studies by physiological data, it is evidently thought by publishers that interest in this direction is increasing. Four books on vocal physiology and hygiene have within a short time been published and brought to our attention. These have been made enticing to the public by elaborate cuts showing sectional views of the throat, protruded tongues, and the chordæ vocales at every possible angle. After the first shudder, which is the tribute to science of the æsthetic sense, perhaps such works will incite to studious interest. There are still a number of theories to be settled and facts to be contributed to the subject of the production, training, and care of the voice.

THE NEXT MEETING OF THE STATE SOCIETY.

The next meeting of the Medical Society of the State of New York will be held at Albany, commencing Tuesday, February the third. In another column will be found a list of some of the papers which will be read. Judging from the programme, it is safe to predict a successful meeting. The topics to be discussed are of sufficient variety and interest to meet the wants of every member.

We need not remind those who may have lengthy papers, of the necessity of presenting them in abstract; nor is it necessary to hint to such as may discuss them, to make their remarks brief and to the point. The long papers, which should of necessity be few and far between, may appear in full in the journals or Transactions; but all the points necessary for practical discussion can be brought forth in the

abstract. There used to be a good rule in this Society requiring the proper division of time upon papers and discussions, and many of the members will recollect how frequently the venerable Clarke, in his peculiarly humorous way, would remind the members of its value. He was right every time he spoke upon the subject, and if his precepts live after him, and the readers of the papers before this or any other society are willing to follow them, what interesting and profitable occasions may be the meetings of all our societies!

DOCTOR VS. APOTHECARY.

It is a notorious fact that many druggists use the prescriptions sent in by physicians over and over again. This they do to their own advantage and the detriment of the physicians. It is very well known also that druggists themselves prescribe not at all rarely, especially for venereal diseases. It is a fact, in the third place, that druggists do not always put in the drugs exactly as given, or else they substitute poor drugs, and that they charge so enormously for the prescription as to make it difficult for the patient to pay both druggist and doctor.

These are old abuses, but they have recently been commented on again, and very strongly, by the *New Orleans Medical and Surgical Journal*, and the *Louisville Medical News*.

Now, the physician is the best friend the druggist has, and it will be wise for the latter to bear the fact in mind. There is a limit to the imposition to which the profession will submit. It is suggested by the *News* that a co-operative society of physicians, buying its own medicines in convenient and elegant form at wholesale prices, and furnishing them at cost to its members, might be a means of saving both physicians and patients no little money. Whether such a scheme be practicable or not, it is certain that something will eventually be done in this direction unless the druggist mends his ways.

STATE HOSPITALS AND STATE COLLEGES.

In an address on State Medicine (*Cincinnati Lancet and Clinic*), delivered by Dr. Thad. M. Stevens before the Tri-State Medical Society, Nov. 5th, the subjects of hospital organization and medical education were taken up. After enumerating the many deficiencies in these, he suggested as a remedy in many States the organization of State hospitals, and with State medical colleges attached. He emphasizes the conclusion that: "with a State hospital well constructed and well equipped for the wants of patients, and a State medical college, with privileges to be derived from such hospital, managed by a competent and industrious corps of teachers; with a board of examiners not in any way connected with the college upon whose certificate diplomas are given—with such a system a higher and better medical education would be insured."

There cannot be any doubt about this. But how is this particular phase of the ideal to be attained in States where colleges and hospitals are already firmly established and, in part, endowed? And this includes nearly every State.

REPORT OF THE HEALTH OFFICER OF THE PORT OF NEW YORK.

Dr. S. D. Vanderpool has made the annual report of his work to the Quarantine Commissioners. The number of foreign ports at which yellow fever prevailed last season, together with the epidemic in Memphis, made the duties of the Health Officer particularly onerous. During the past year, ninety-five vessels which had yellow fever on them, or had had the disease previously, arrived at this port. So persistent has the disease been at some of the West Indian ports that vessels infected with yellow fever continued to arrive here until the end of the year.

Two hundred and fifty-six cases have occurred on the infected vessels. At the Quarantine Hospital twenty-nine cases of yellow fever were treated, of which eleven died. In addition, twenty cases of malarial fever were in the same hospital.

Only seven cases of small-pox arrived at the port during the year. The practice of making a preliminary examination of emigrants before sailing now prevents the introduction of this disease.

Dr. Vanderpool discusses the methods and practicability of disinfecting infected vessels. A number of plans have been proposed for this object, but there are three principal ones: the refrigerating process, that by superheated steam, and that of sealing a vessel and then pumping in large quantities of air, so that by a process of oxydation the materies morbi may be destroyed.

Dr. Vanderpool is willing to admit that the methods may in certain cases accomplish their object, but he asserts that practically they are inapplicable and valueless. They would involve a delay and an additional expense, which would amount to an obstructive quarantine. Referring to the proposed refrigerating plan, he doubts very much whether it would at all insure the destruction of the germs.

On the whole, he believes that the present method of quarantining, lightering, thorough cleaning, and disinfection with sulphurous acid, is sufficient and is all that can be undertaken without paralyzing our commerce with southern ports.

Last summer a case of yellow fever, in the person of the stewardess of a vessel, in spite of quarantine, got into the city, and was sent as a case of malarial fever to the Presbyterian Hospital. The vessel on which the patient had sailed came from Havana, and had several cases of malarial fever on board. After the five or six days' trip from Havana, and ten days'

quarantine, no yellow fever appearing, the vessel, having been cleaned and disinfected, was sent to the dock. Ten days later the case of yellow fever referred to broke out. As the period of incubation of yellow fever rarely exceeds five or six days, and as the vessel had been, it was supposed, thoroughly cleansed, the appearance of the fever was very puzzling. Dr. Vanderpoel states, however, that, having had the vessel sent back to quarantine, he made a more thorough examination of the hold. He found that there were no niches in the framework on either side of the keelson. These niches ought to be present, and, when they are, they allow the foul matters that run down between the ribs to flow on into the well, whence they can be pumped out. In this vessel there was a great deal of filth found to have accumulated. This was removed, and there have been no cases of yellow fever on the vessel since.

No better illustration could be given of the necessity and usefulness of cleanliness for the prevention of yellow fever, whatever other measures be resorted to.

As regards special measures of disinfection, Dr. Vanderpoel seems to be correct in his opinion that none of these methods referred to can be adopted, as in the ordinary routine of quarantine duty. It is not unlikely, however, that superheated steam can be employed with success in certain special cases where prompt and thorough disinfection is desired. No method of disinfection, however, can be more than a supplement to thorough cleansing.

Dr. Vanderpoel's success in protecting this city from yellow fever during the past year, without obstructing commerce, is a matter that redounds greatly to his credit. The skill displayed and the care necessitated to secure these results cannot be too greatly praised or too highly appreciated.

KEEPING CHILDREN AFTER SCHOOL.

Physicians will commend the very sensible view taken in *Good Company*, on the subject of keeping children after school. For some trifling breach of discipline, numbers are obliged to remain in the bad air of the school-rooms, when already exhausted by the day's confinement. School-houses are thus turned into penitentiaries, and some of the children, perhaps, into invalids. It is well enough to use this means of discipline occasionally upon the healthy and vicious. But thus to confine the very young or the delicate beyond the usual hours is a practice liable to cause serious injury. Teachers are to remember that an education gained at the expense of health is of no value. And the importance to the growing child of keeping in the best physical condition should be borne in mind in matters of discipline as well as of instruction. Then, again, the teacher suffers as much as the pupil. This consideration alone should make the practice unpopular.]

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Dec. 24, 1879.

Dr. E. L. Keyes, President, in the Chair.

A TRACHEOTOMY-TUBE WORN FOR SEVENTEEN MONTHS WITHOUT INJURY.

Dr. Beverley Robinson presented a patient upon whom he had performed tracheotomy two years ago. His object in so doing was to illustrate the fact that a tracheotomy-tube could be worn for seventeen months without any injury to the trachea, and that the function of the latter, as well as that of the larynx, could be perfectly restored after the healing of the wound. The history of the case had been presented to the Society on a former occasion.

MYOFIBROMA OF UTERUS OF LARGE SIZE.

Dr. J. C. Peters presented a specimen of myofibroma of the upper and posterior portion of the uterus from a lady aged 37 years. The patient, married five years, had been apparently in perfect health up to eleven or twelve weeks ago, when she became unusually fatigued while standing at a funeral. There was no evidence that she caught cold on that occasion. Shortly after she suffered from a great deal of pain and discomfort. Dr. Peters was then sent for, and found on examination that the os uteri was under the pubes, also what he thought to be a retroverted womb containing a fibroid tumor. The organ was quite firmly fixed, and was packed tightly in the pelvis. After considerable effort Dr. Peters succeeded in dislodging it, thus relieving somewhat the effects of the previous pressure. The patient was benefited somewhat by this procedure, so that she could change from the recumbent to the sitting posture. Being absent from town, Dr. Peters did not see her again for a fortnight. In the meantime she was examined by one of the leading gynecologists of the city, and shortly afterward a miscarriage was the result.

After the miscarriage the cavity of the uterus appeared to be clean, but, as the sequel showed, a portion of the placenta remained, giving rise to a very offensive odor. The mass was promptly removed. Peritonitis next occurred, and the patient died in ten days.

Dr. Peters remarked that the interesting points were, the difficulty in diagnosis, the peculiar position of the tumor, its size, rapidity of growth, and the supposition that it was undergoing sarcomatous degeneration.

ANEURISM OF BASILAR ARTERY—RUPTURE AND SUDDEN DEATH.

Dr. Amidon exhibited a specimen of aneurism of the basilar artery, from which hemorrhage occurred, causing almost instant death. The patient was a male, aged 44.* There was a history of alcoholic indulgence for many years until four years ago, when he almost had delirium tremens. Fifteen years ago the patient had a chancre, which, with the secondary and constitutional symptoms, were thoroughly treated by the late Dr. J. O. Stone. The last syphilitic symptoms were seen at least twelve years ago.

* The case occurred in the practice of Dr. J. H. Emerson.

Five years ago, while at table, he had a fit with loss of consciousness, clenching of the hands and frothing at the mouth. No other seizure was known.

December 17th, while in his office, he "fainted," fell off his chair to the floor, and came to himself slowly, remaining confused and dull. Under Dr. Lewis's observations, since the seventeenth, there has been gradual improvement in the mental condition of the patient, who was still stupid, but presented no objective symptoms. The urine was normal.

December 20th. Has been improving steadily. He denies headache or dizziness. Patient was seen in consultation by Dr. Seguin. The walk is correct, but feeble. Speech slow, vocal clear, pupils equal and active, fundus of the eye normal. No paresis in face or body. Heart normal, pulse slow, less than 70; has been slower. There was a flattened node on the right tibia. A *diagnosis* was made of cerebral syphilis.

December 21st. The patient was seen by Dr. Emerson at —o'clock, and seemed still better. He had gotten up of his own accord and washed himself. Except his pallor and slow pulse (65), there were no objective symptoms.

A few minutes later the patient lay down upon a sofa, made some noise which attracted his relatives, and almost instantly expired, without convulsions.

Autopsy twenty-seven hours after death. The skull was of extraordinary thickness. On removing the brain, as soon as the optic nerves were cut by the knife, considerable semi-fluid blood welled up.

After the brain was removed the entire interpeduncular space was seen to be filled with pretty firm blood-clots. These covered also the anterior surface of the pons and medulla, and extended far down the anterior surface of the spinal cord. The hemorrhage was entirely intra-meningeal in location, the brain seeming not lacerated anywhere.

The source of the hemorrhage was found to be a small aneurism (size of large bean), situated at the bifurcation of the basilar, a little to the right of the median line at the anterior border of the pons Varolii. There were no miliary aneurisms, and the arteries presented a nearly normal appearance.

Dr. Seguin remarked that when he saw the patient the latter was absolutely free from any symptoms, save those referring to slight sluggishness of mental action. He could use words correctly, walk perfectly straight, and had possession of all his faculties. At the time Dr. S. thought that the mental sluggishness might have been due to the epileptiform convulsion which the patient had suffered a short time before. He confessed, however, that he had not found the cause for a similar attack which had occurred to the patient five years ago, unless it was possibly due to the basilar aneurism which may have occurred at that time and created the necessary interference in the circulation of the circle of Willis.

Dr. Peters remarked that there were ten or twelve cases of aneurism of the basilar artery in the records of the Society, attended with rupture.

Dr. Seguin asked if death had been sudden in those cases.

Dr. Peters did not recollect.

Dr. Seguin remarked that there were cases on record in which death had occurred almost instantaneously. He was aware that such a possibility was denied by some authorities. In the present case death must have occurred in a very few moments.

Dr. Satterthwaite said that hemorrhage into the medulla, even though it were of small amount, might cause instant death.

Dr. Amidon referred to two cases of extensive cerebral hemorrhage in the lateral and fourth ventricles, in which the patients lived twenty-four hours.

CEREBRAL HEMORRHAGIC PACHYMENINGITIS.

Dr. Seguin presented a specimen of cerebral hemorrhagic pachymeningitis with the following history:

CASE OF CEREBRAL HEMORRHAGIC PACHYMENINGITIS.

Mr. X——, æt. 68, a merchant, seen on September 19, 1879, with Drs. Abbe and Herrick. The patient's general health had been excellent for years. In July of this year he had what was called a partial sunstroke. About the last week of August returned from a trip to Colorado, looking badly.

A few days after return, a "neuralgic" headache set in on the right side, and has continued, with intervals of from two to five days, until now. Within ten days from the beginning of this headache a most remarkable failure of muscular strength, not of paralytic form, manifested itself. Pain has been very severe, and more generalized (less neuralgic) in the last three or four days; severe at night. Since the 17th (two days ago) great restlessness, physical and mental apathy and failing strength, have been observed. No aphasic symptoms. A more important symptom has also appeared, viz.: a slight stiffness, with occasional clonic spasm of the right arm and hand. The right cheek has been thought flabby. Mr. X. has been indisposed to use the right arm and leg, and has preferred to lie in bed. The pulse, in the last two days, has risen to between 70 and 80, after having been slower. The axillary temperature has risen to 99½° F. Memory unimpaired; no albuminuria. Pain in head now diffused and frontal.

Examination.—Patient lying on his back, with his right forearm and hand in the semiflexed and adducted position, characteristic of contracture. Intelligence preserved; answers are slow, but correct, yet patient is indifferent and dull. Pupils normal; right orbicularis palpebrarum is the seat of constant clonic spasms, which extend to frontalis and other facial muscles. No twitching of right hand during the visit. Moves all limbs voluntarily, but extension of right arm and hand is incomplete, and there is marked rigidity to passive motion at elbow and in fingers. Mouth is drawn a little to the right (spasm); tongue is projected straight; articulation good; uses words correctly. No cardiac murmur, second sound hard, arteries tense; no redness on nates. In last two days involuntary, and, to a certain extent, unconscious micturition; patient is now wet without knowing it. No retention. Was always right-handed.

The symptom diagnosis was partial right hemiplegia, and it seemed to me that the most likely anatomical cause of such a peculiar paresis with hemispasm (face) was gradual interference with the blood-supply of the motor area above the speech-centre on the left side. I expressed the opinion that Mr. X. had atheromatous cerebral arteries, and that the terminal branches of the left Sylvian artery were blockaded. I anticipated gradually increasing hemiplegia.

I did not again see the patient alive, and I am indebted to Dr. Abbe for notes.

On September 20th, contracture of the left forearm and hand appeared, both arms being similarly stiff and semiflexed; they were occasionally drawn up by spasm. Vomited.

Sept. 22.—Increased drowsiness; both arms con-

tractured. Complains of head feeling hot inside (cool outside). Lucid intervals. No anæsthesia. Temperature in axilla 100.5° F.; pulse 110.

During the last thirty-six hours of life the symptoms were profound drowsiness, absolute loss of vision. He occasionally whispered, and when asked if he heard what was said about him, said yes.

It is now stated that on September 18th (the day before I saw Mr. X.) he used the wrong words a few times, saying, for example, "diasnosis" for "diagnosis," etc. Mental action remained clear, but slow, until the last few days, when deep coma set in. During the last three or four days of life (even while some consciousness remained), sight was lost. To the very last of life the pupils were small and fixed. The pulse was abnormally full and slow from the onset of the disease (I found it *tense*), beating regularly from 58 to 60 a minute. At the time of consultation, six days before death, it was higher, nearly 80, and rose to 110 or more in the last three days. Slight fever was observed in the last few days.

The patient lived perhaps one month after the onset of the peculiar cephalalgia.

Sept. 25.—Died comatose.

Autopsy made 24 hours post-mortem. Head only examined. While removing the calvarium two unusual phenomena occurred. When the sawing was nearly done a small hole was made in one temporal region through the dura mater, and from this, through the line of sawing, a fine jet of dark blood came out with extraordinary force, not per saltum. When the skull-cap was torn off (with great effort, as the dura was closely adherent to the calvarium), the dura gave way in the frontal region, and a perfect torrent of dark liquid was forced upward and backward, drenching the operator, striking his face, and some of it reaching three or four feet behind the head upon the floor. No one present (Drs. Herrick, Abbe, Amidon, and myself) had ever witnessed such an occurrence.

It was soon seen that this escape of liquid blood was from the cavity of an immense double hæmatoma; a large amount of fluid blood and some sheet-like clots lay in cavities formed externally by the dura mater and internally by a false membrane, united at its margins to the dura. There were thus two sacs extending over almost the whole of the superior and lateral aspects of the cerebrum. These sacs extended from the outer border of the anterior fossæ to the tentorium cerebelli, being thickest at about their middle, *i. e.*, over the fissures of Rolando and Sylvius, and the adjacent motor convolutions, thinning off in all directions. It seemed to me that there was but a thin sheet of clot and membrane over the posterior part of the third frontal convolution on either side. Judging from the violent irruption of blood which occurred on opening the skull, it seems evident that the liquid blood in the sac must have been under enormous pressure. Another proof of this lay in the remarkable deformity which the cerebrum presented, the hemispheres in their upper median regions being concave instead of convex. The greatest depression below the normal level of the convolutions was estimated by those present at about 18 mm. or two-thirds of an inch. The excitable districts on both sides—the centres for the forearm and leg, according to physiologists—were the seat of greatest depression. The speech-centre seems to have escaped direct compression. The arteries at the base of the brain and in the fissures of Sylvius were normal. The arachnoid and pia were everywhere healthy; not opaque or adherent to the false membrane. The brain was not cut, as I desired to preserve the cerebral deformity, which for an hour did not vary. In hardening, the whole brain was somewhat distorted and the depression made to seem less.

The Society the went into executive session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 8, 1880.

FORDYCE BARKER, M.D., LL.D., IN THE CHAIR.

THE Academy was called to order at 8.15 P.M., and the minutes of the last stated meeting were read by the Secretary, DR. H. T. HANKS. The President announced the completion of the fusion of the Medical Journal Association with the Academy, and stated that he believed every one who had the interests of the profession at heart, must regard it as a consummation that would be of great advantage to the profession, not only in the present, but in the future. He then announced that the polls were open for the annual election of officers. Dr. Janes presented the report of the Committee on Admissions, which contained the names of a large number of applicants. Prof. Mayer, of the Stevens Institute, and Prof. Rood, of Columbia College, were introduced to the Academy, and invited to take seats on the platform.

THE GRAPHIC METHOD, AS APPLIED TO PHYSIOLOGICAL RESEARCH.

DR. J. W. S. ARNOLD addressed the Academy upon the above subject, and demonstrated how exactly certain physiological phenomena can be observed and recorded by this method, which reduces experimentation, in all its most difficult detail, to writing, and thus enables the experimenter to obtain an exact knowledge of the most complicated phenomena. The principles involved, and the various pieces of apparatus employed, in applying this method to physiological research, were then enunciated and described. The simplest conditions for measuring time occupied in travelling distance, is measuring the time consumed in going straight from one given point to another. Fractions of the time, in that instance, represent fractions of the distance, provided the rate of travel is uniform throughout. This straight line, ———, is the *abscissa*, and represents the time occupied by a continued act or movement. If a lever at rest makes such a line, and it be moved away from the direct line, the indication is, that something has impinged against some other part of the lever, and given *motion;* if the line of deviation is *oblique*, it represents a slow movement, and if *abrupt*, a rapid movement. These lines are called *ordinates*. By the aid of the abscissa and ordinates we are able to interpret nearly all the phenomena belonging to physiology, where the graphic method has been employed. The method is especially valuable in physiology, in studying muscular movements, particularly the complicated movements of the cardiac muscle (see MEDICAL RECORD, vol. x., p. 289 *et seq.*). Besides, all we know at present regarding the rapidity of nervous conduction, the time occupied in transferring impression into action, was obtained by the application of the same principle (see vol. x., p. 497 *et seq.*). The first piece of apparatus required is a travelling surface, moving at a uniform rate, and the most convenient is the cylinder devised by Ludwig, and since modified by several physicists. The next is a mechanical writer, to make

the respirations, and this must move with the least possible amount of friction upon the recipient surface which is to receive the impressions. The cylinder is usually covered with white glazed paper, or else with a tallow candle. The most complete writer, doubtless, is that known as Marey's *drum cylinder*, which consists of a small drum-barrel, over the top of which is stretched a piece of fine india-rubber, and to the side of which is attached a rubber tube that communicates either directly or indirectly—usually the latter, and through a second drum—with the lever which is to do the writing on the moving cylindrical surface.

One of these drums can be placed over the apex of the heart, and, the impulse being communicated to the rubber cover, displaces a certain amount of air, and thus transmits the impression to the writing lever attached, and a line indicating motion is made upon the smoked surface. Not only that, but the respiratory movements of the chest, by the aid of accessories, may be recorded at the same time, and thus after I opportunity to study the exact relations which the apex-beat, and its rhythm, have to respiration.

The double canula, or sound, devised by Marey, was then exhibited and described, by which a record can be obtained of what is going on within the cavities of the auricle and ventricle at the same time. It is introduced readily through an opening in the jugular vein of a horse, and passed down until one portion rests in the auricle and the other in the ventricle, and that without apparent discomfort to the animal. The sphygmoscope was then described, and the method of obtaining, at the same time, a registration of the comparative amount of force developed in different parts of the body.

Having obtained an inscribing and a receiving apparatus, *accurate measurement of time* became an important consideration, and that was secured by means of the tuning-fork, an instrument already known to vibrate a certain number of times to the second—the higher the pitch the greater the number of movements, or vibrations. The manner in which the tuning-fork used can be verified by the graphic method was explained, and the working of the various pieces of apparatus mentioned was shown. The *myographion*, or muscle-writer, was then described, including Marey's method of producing an *imbricated* tracing (see MEDICAL RECORD, vol. x., p. 200). An ingenious device, by his accomplished assistant, Dr. Maurice N. Miller, for the more convenient performance of the experiment of obtaining a record of the movements of a muscle of the frog's leg, was then described and illustrated upon the screen. The manner of measuring nerve-conduction was described, and the possibility of measuring the time occupied, before the movement occurs, after the brain wills that the right or the left hand shall move. The rapidity, therefore, with which thought travelled could be measured, and it had, when compared with certain movements in the physical world, been found to be quite slow. "Quick as thought," was, in comparison slow. Dr. Arnold then referred to the sources of error in the graphic method; how well they were already understood; how completely they had been obviated; and how unnecessary, at the present time, it was to be inaccurate, either in experimentation or demonstration. He believed it to be impossible to study advanced physiology without being familiar with the graphic method, since so much had been learned by it, especially in the schools in Leipsic and Munich.

The President extended the thanks of the Academy to the speaker, and invited Dr. John C. Dalton to open the discussion. He regarded the graphic method as one of the most important means for improvement brought forward within the last fifteen or twenty years. He regarded it as a means of making observations, and appreciating certain phenomena in a distinct, certain, precise, and positive manner, which we could not do without it. Ever since we had studied physiology, as the physicist studies physical science, advancement has been made; and one of the most important and useful aids we had called into our service was the graphic method. He was exceedingly glad that Dr. Arnold had been the one selected to bring the method forward that evening, for he had had more experience, and was more dexterous in its application, than any one in this neighborhood, certainly in the ranks of the physiologists. There is a little difficulty at first, in understanding the method, as for example, when we look into a book upon physiology, and see represented what are called abscissæ lines and ordinates, but if we would stop and think that one was horizontal and the other vertical, that the first means time, and the second means movement, the study was much simplified. Then there was the difficulty of keeping in mind the meaning, if we simply looked upon the tracings as they appear upon the page of a book, of the different curves placed there, mixed together—the ordinates and the abscissæ; but, having once seen the instruments work, and seen the tuning-fork mark the time, and the lever drawing up, there was no further difficulty in understanding it.

There are so many movements in the human body which follow each other with such rapidity that our unaided senses are incapable of catching and retaining them; and when we come to study the phenomena incident to such movements, the importance and usefulness of the graphic method at once becomes apparent. Its usefulness, however, depends entirely upon its accuracy. If the instruments record the movements correctly, they are valuable, but if they record them incorrectly, they are worse than nothing. This point has not been neglected. It is very easy to see many of the sources of error in their use—as, for example, the writing-levers are usually rods of certain length, working upon a hinge and writing upon a surface, and the work cannot be performed without friction, and friction retards movement. Has this been taken into consideration? So, also, the lever is pushed up by a certain force, and may it not make a record beyond the point which represents exactly the pushing force? Again, in consequence of being a lever working upon a hinge, its writing extremity cannot possibly move in a vertical direction, but it moves in the arc of a circle. The elasticity of the drum-heads, the tubes, and the air which is contained in them, the elastic material in general, etc., are all important factors which may affect the accuracy of the observation. The question naturally arises, is there any way of correcting these inaccuracies, and is there any method by which we can tell whether or not we are making correct observations and doing accurate work? All these points have been thought of and provided for; and Dr. Dalton then explained at some length how the inaccuracies had been overcome by removing the sources of error; so we may now feel satisfied that the knowledge we obtain from these instruments is important, and it is truthful. Certainly, a great deal of skill is required to use them properly. He referred to the experiment upon

he heart of the horse, and spoke especially of the eeming entire lack of sensitiveness when the canula s introduced into the cardiac cavities.

The discussion was continued by Prof. Mayer, of he Stevens Institute, who added the fact that the graphic method had been so perfected that it showed when the investigator was upon the right and when upon the wrong track. He spoke of the method of letermining how long the sensation of sound remains after the exciting cause has ceased to act upon he tympanic cavity.

Prof. Rood, of Columbia College, while somewhat familiar with the use of the graphic method in physics, was not at all familiar with its application to physiological research; yet, regarding the reliability of observations made by the method, he could corroborate all that had been said upon that point. He also referred to the fact that an American had been one of the most active workers in the world upon he physical portion of the question, and had reached a precision in knowledge regarding the number of vibrations which tuning-forks make to the second that had been sought and patronized by the most scientific men of the Old World—Prof. Mayer, of the Stevens Institute.

The discussion being closed, the Academy proceeded to the transaction of unfinished business, after which it adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 22, 1879.

Dr. A. E. M. Purdy, President, in the Chair.

The Society was called to order at 8 P.M., and the minutes of the last stated meeting were read by the Secretary, Dr. F. A. Castle.

"THE ORGANIZATION AND OPERATIONS OF THE NATIONAL BOARD OF HEALTH,"

was the title of a paper read by Dr. John S. Billings, U. S. Army, and Vice-President of the National Board of Health. The speaker omitted the consideration of the general plan of the organization of the National Board of Health, with which the profession had been made familiar, also the history of its operations during the past year, which would soon appear in the annual report; nor was it his purpose to reply to the objections to the existence of the organization, for the opinions of nearly every important sanitary organization had been expressed emphatically that the National Board of Health should be continued substantially as it is now, and therefore he regarded it as a waste of time to discuss the latter point. The principal object of the paper was to bring up for discussion the vexed subject of "national quarantine." Preliminary to the consideration of that question, Dr. Billings reminded his audience of the forms of public health organization in France, Germany, and England.

In France the public health organization not only takes into consideration measures of quarantine, but such questions as the propagation of vaccine, the inspection of mineral waters, and the qualifications of the inspectors of the same, both medical and pharmaceutical, sanitary police, questions to be submitted to the Academy of Medicine, members of special commissions, etc., etc.

In Germany a public health organization was established in 1875, simply as a board for counsel and advice. One of the chief objects of the board was to elevate public hygiene into a science, and to submit propositions in connection therewith.

In England the board of public health has nothing to do with quarantine, strictly; in fact, England has no system of quarantine.

In the United States the main purpose of the National Board of Health is to collect information and give advice relating to sanitary matters, and like other powers mentioned in the act giving it an existence.

The essential difference between the board of health in France and that in the United States is, that in this country the board is not obliged to wait until it is asked before offering advice. It was not *a* board to collect and furnish information with reference to various sanitary questions, but it was *the* board, and it did not seem advisable to make any change in the form of organization at present.

The practical point of public hygiene must rest upon utilitarianism, and, to be most effectual, its work must be carried on with the least interference with commerce, travel, and with the least conflict with local self-governments and the general interests of the public. Such a work must be essentially of the nature of a compromise; for, the local interests of such a country as ours vary with varieties of climate and latitude, education and habits of the people, etc. In the United States such a public organization should be as elastic and flexible as compatible with stability; indeed, such flexibility was essential to its stability. One of its most important functions was *educational*. Sanitary science was a new thing in this country; but few had paid any special attention to it. It was popularly supposed that *all medical* men were sanitarians, and when they were appointed to fill places in health boards, all had been done that was possible to preserve the health of the locality in which such boards were organized.

The topics for observation were many, but the qualified observers were but few. Certain statistics were needed for the benefit of public hygiene, and their *value* must of necessity depend upon the knowledge which the general medical practitioner possessed. The National Board of Health, by its publications, by the education it could give through the public and the professional press, could and should give a favorable stimulus to the processes of sanitary education, and could be the means of saving a vast amount of money to the country by its recommendations. A very important part of the higher education of modern times was to teach how to obtain the higher knowledge, and the best way to teach was to perform the work and show the people how it could be done.

With reference to quarantine, the old idea of *detention* should be rejected. Quarantine was defined as a system of administration employed to determine the presence or absence of causes of contagious or infectious disease existing either in persons, articles of clothing, or vehicles of communication; to secure the destruction of the morbid elements, and the removal of such causes; and to do so with the least possible interruption to travel, etc., and with the consumption of no more time than is absolutely necessary for purposes of inspection, cleansing, and disinfection.

Two changes had been suggested with regard to the National Board of Health. First, that the board should have a single officer. Those who maintained that opinion were decidedly in the minority. The majority of sanitarians did not think it proper to

place so much responsibility and power in the hands of a single individual. Second, all the good results could be obtained by establishing a small executive committee which should be constantly on duty and acting under instructions. The mouthpiece of a national board of health must be stronger than if he were a sole officer.

The speaker then passed to the consideration of the fact that no satisfactory quarantine establishments existed on the Atlantic coast south of Philadelphia. In view of the poor inland quarantine in this country, notwithstanding the feeling in some Northern ports that because they have provided themselves with efficient quarantine accommodations, other ports should do the same, it might be well not to be too grudging in furnishing means to protect our brethren of the South. The bread cast upon the waters might return.

There was an abundance of subjects for legislation relating to the pollution of streams, sources of water-supply, adulteration of food and drugs, diseases of domestic animals, hygienic management of public buildings, and the collection of vital statistics. The estimated cost of placing the quarantine stations along the Atlantic and Gulf coasts in good condition, now, was $185,000. In addition to what now exists there would then be required $200,000 for annual expenditures. In addition to the regular annual expenditures, $100,000 should be in fund to be used for emergencies, such, for example, as that which had been encountered within the past year.

In connection with the estimates, two practical questions arose: 1. What results can be secured by such an investment? and 2. Would the investment be judicious and remunerative? The result would be: 1. The prevention of the occurrence of some epidemics of diseases, such as yellow fever, cholera, plague, typhus fever, and small-pox; 2. The securing of such an amount of education for the people as would induce the taking of measures to obtain abundant power in all localities to obtain a diminished amount of sickness and mortality; and 3. A natural increase in such knowledge of disease as would afford the most economical means of destroying its causes.

In conclusion, he appealed to the medical profession to aid in the great work.

The paper was accepted, and being before the Society for discussion,

Dr. S. O. Vander Poel, Health Officer of the Port of New York, on invitation, remarked that from necessity he had been not only familiar with the organization of the National Board of Health, but had watched its work with the greatest interest, and at times with jealousy. When the measure was first proposed it came from a source which did not inspire him with confidence, and tacitly he was opposed to it; but when the appointing power was placed in the hands of the President, he at once, and had ever since, given the organization his hearty co-operation. The amount of work which had been done by the board since its organization had been immense. We were apt to form our estimates of the duties and labors of such a board upon different European models, but then they had none of the difficulties relating to climate and habits which met such an organization in this country.

Again they had had to contend with the jealousy with which this country regards central organization as exhibited among different States. The work which they had performed was justly entitled to the respectful consideration of the medical profession of the country.

In some respects he might not agree with the National Board of Health. Its duties were, to a certain extent, administrative, but he believed success depended more upon the character of the men to whom the trust was confided, than upon the mere arbitrary execution of the law to which they were subject. So long as the gentlemen administered the law fairly, frankly, and justly, they could to a great degree, conciliate and keep dormant the prejudices which naturally rise in every locality. The obtaining of sanitary surveys in this country was one of the most important duties of the National Board of Health. A thorough knowledge of the sanitary condition of every locality would enable it to act more promptly than it otherwise could do in cases of emergency, and under circumstances requiring immediate action. He suggested the division of the coast quarantine system into districts, making one station answer for two or more ports, which would be a saving for the ports and the general commerce of the country. For example, a station at Fort Monroe might answer for Richmond, Washington, Baltimore, etc.

He thought a duty which the Society owed to the National Board of Health was to give it its full and hearty co-operation, and hoped the paper would be referred to a committee which would report upon it fully at some future meeting.

Dr. Ezra M. Hunt, President of the Board of Health of the State of New Jersey, on invitation, spoke of the relation existing between the medical profession and public health and sanitation; and believed that the arguments which established State Boards of Health should establish a National Board of Health. The greatest values were from the largest numerical data, and it was only through that channel that the greatest number of facts could be reached. He thought the work of the present National organization had done more towards settling the question of State and National sovereignty than had been done by politics during the past ten years. Congratulatory remarks were continued at some length.

Mr. Jackson S. Schultz, merchant, on invitation, spoke of the relations existing between public sanitation and commerce. Out of the yellow fever epidemic which occurred in New York in 1822, certain errors grew with regard to the subject of quarantine, and those who were so unfortunate as to be engaged in the rejected trades, such as in hides, rags, etc., were prevented from doing business up to 1840, and at a loss in money to the city of New York of at least $100,000,000, a sum which would have paid for a board of health from that date up to the present time. If these trades apprehended that they were to be stopped at any time, they would be willing to contribute, and could afford to contribute, to the building of hospitals and the founding of schools in which men could be educated in the methods of meeting the invasions of contagious and infectious diseases. He also thought that Congress would not hesitate to appropriate the money needed, if properly influenced by the medical profession regarding the necessity for such an expenditure. He also spoke of the accord existing between the health officer of the port of New York and the merchants, and of the feeling of the merchants that, if there was any danger of returning to those old practices, they would be willing to maintain not only a State, but a National Board of Health, for the purpose of promulgating correct views regarding public sanitation.

Dr. A. Jacobi, agreeably to the suggestion made by Dr. Vander Poel, moved the appointment of a committee to report upon the paper of the evening

at some future meeting. In all our affairs, political or otherwise, we were too apt to be directed by the democratic feeling that no one except ourselves should have to do with the direction of our affairs. We were very apt to overlook the fact that we depended upon the nation, and the nation upon us. We had always been opposed to centralization, always forgetting that centralized means are always required to accomplish great ends. When the study of that fact was closely followed, it would do much towards removing many of the prejudices now existing relating to the National Board of Health, and also special boards of health. It should not be forgotten that our country was smaller than it was fifty years ago; that is, the facilities for travelling and for communication were so great that distances had diminished in importance to such an extent that the remotest parts of our country were quickly accessible. All these considerations should enter into the formation of a report for such a committee.

The motion was adopted.

Dr. E. Seguin then read a scientific communication upon the Metric System, which was accepted and ordered on file.

The report of the Special Committee on the Yellow fever Fund was read by Dr. Wm. M. Chamberlain, after which the Society proceeded to the election of one delegate to the State Medical Society, to fill the vacancy caused by the death of Dr. Freeman J. Bumstead.

Dr. C. S. Bull was elected to fill the unexpired term of three years.

On motion by Dr. J. C. Peters, the thanks of the Society were extended to Dr. Billings for his interesting and valuable communication.

The President announced that at the stated meeting in January, Dr. Fordyce Barker would read a paper on "Puerperal Malarial Fever."

The Society then adjourned.

Correspondence.

SURGEONS IN PUBLIC JOURNALS.

To the Editor of The Medical Record.

Sir:—The Record never intentionally wrongs any one, but your remarks in last week's issue (Jan. 10th), under the above caption, do such injustice to my friend, Thomas Keith, the great Scotch ovariotomist, that I must beg you to let me say a word in his defence. I know Dr. Keith well, and I can truly say that a more modest, reticent surgeon never lived. He is the last man in the world to blazon his wonderful works before lay readers; and I am sure he had no more to do with the publication in the *Scotsman*, of which you complain, than you or I had.

But I do not wonder that his countrymen are proud of his achievements, for his record as an ovariotomist is simply marvellous; and their egotism is pardonable when we recall the fact that from the beginning his success far surpassed that of all other surgeons, and that since his adoption of the antiseptic method his cures amount to ninety-seven out of a hundred, while in one continuous series he had seventy consecutive successful operations without a death.

If such work as this does not justify his countrymen in a little hero-worship, I should like to know what would. Must Thomas Keith die before we shall dare to speak his name above a whisper outside the ranks of the profession? In our country, yes. But not so in Great Britain; for there a man of Keith's modesty and merit is always fully appreciated by his brethren: they feel themselves and their profession honored by his noble deeds, and they are not afraid to let the outside world know it. What harm can possibly come to the profession by the *Scotsman's* article on Keith's character and labors? It does not advertise Keith, for he is known in every household all over Scotland. It does not send him a patient he would not get without it. No. The labors of Keith ennoble medicine in the eyes of the world, and it is eminently proper that they should be spread before the world, and in the manner that Scotland's great newspaper has seen fit to do it.

Keith's success is not to be explained away by your query: "Was there no selection, no turning over of doubtful cases, no refusal to give a patient the very last chance?"

From my personal knowledge, I can assure you that Keith never selects his cases, never turns away doubtful ones, and never refuses to give a patient the last chance.

He operates on all that come to him, if there is the slightest hope whatever of saving life.

On the 1st and 4th of July last, I saw him operate on two almost hopeless cases—certainly hopeless before the days of Listerism. The adhesions were universal, and of the worst kind. In one he used drainage; in the other not. Each recovered promptly, and in each the pulse never rose over 99, nor the temperature over 100°.

You ask, "Have we a genius who never fails in diagnosis, who can foresee every contingency, and meet every complication with unerring judgment?"

I answer yes; but Keith is not a mere genius. He is greater than a genius. In diagnosis he is always clear and positive. He foresees and is ready for any contingency, and he meets complications with unerring judgment. Well may you say, "If so, then humanity should rejoice." But how can humanity rejoice, if we keep a knowledge of this great man's works walled up within the ranks of our profession? If "humanity should rejoice," why should we censure the *Scotsman* for giving humanity the opportunity to do so?

We should not complain of the world's knowing of Keith's great work, for it is the work of just such men that elevates and dignifies medicine in the world's estimation. From our little, narrow standpoint of view, we might fear that this would give a boom to Keith's material interests. That feeling may do for our country, but not for Scotland. For there Keith's merit is acknowledged by all, and there is no one to contest his claims. He stands so high, is so honorable, so noble, so grand, that he has no rivals. In Scotland there is no carping at the *Scotsman's* having spoken so frankly of Keith and his labors. The fact is that the *Scotsman* was simply the mouthpiece, not of Keith, but of his professional brethren, who are proud of his achievements. And there is no doubt that Keith is innocent of all complicity, directly or indirectly, in it.

I speak of what I know, and if we had on this side the Atlantic a little more Scotch liberality and Scotch independence, we would all be the better for it.

Yours faithfully,

J. Marion Sims.

New York, Jan. 15, 1880.

MEDICAL FEES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: There is another side to the question of "Medical Fees"—a side which is left untouched by your editorial articles and the comments of your correspondents. The essential difference between a profession and a trade is that, in the latter, measurable or ponderable commodities or quantities are vended, while in the former services are rendered which cannot be weighed or measured by fixed standards. The tradition of our profession still preserved as a rather poetic fiction by our British brethren—used to be that a physician's skill was beyond price; and the honorarium was not regarded as a cancelling payment, but as a testimonial of gratitude, analogous in this respect to the honorarin even now tendered to clergymen at marriages and christenings. In the beginning, thus freewill offering was made by the patient in proportion to his means, and although custom has since established a certain scale of "fees," the principle remains unchanged, and there is, I think, a grave objection to the phrase "equivalent in money for services rendered," as applied to medicine. "All that a man hath he will give for his life," and it can scarcely be called an "equivalent" when he is called on to disburse the price of a ready-made suit of clothes.

Touching the "itemizing" suggestion of your correspondent "X," it has long been matter of wonder to me that the public and the profession have not discovered the inherent absurdity of charging for the number of visits paid instead of for the service rendered. In the case of a pure consultant who sees each patient but once or twice, a fixed fee is, of course, expedient; but where the attendance extends over a prolonged period, the "visit system" is a direct premium on incompetence or dishonesty. An ignorant practitioner, working on a mistaken diagnosis or with scanty therapeutic lore, will keep his patient under treatment five times as long as would a master of our art; is it fair that he should receive five times as much remuneration? An unprincipled practitioner may multiply unnecessary visits, with a strictly "business-like" single eye to the resultant "items" in his quarterly or monthly account. If any business man had his choice between being cursed in forty-eight hours or being kept ill for a month, with three visits per diem from his doctor, for which alternative would he be willing to pay more highly? Again, it may happen to a physician on the one hand to save a life in a single visit, or, on the other hand, to have to pay a dozen visits to some trivial case which never imperils life; in which instance should he be more highly compensated? Lawyers are wiser in their generation than the disciples of medicine, and usually apportion their fees to the importance of the case in hand; and I can see no reason why our profession should not do likewise, having regard always, of course, to the patient's circumstances. One thing is certain: so long as we consent to degrade the noblest of pursuits to the level of a trade, so long will a certain class of the public persist in looking on us as if we were tradesmen, whose "bills" require as close scrutiny as those of their grocers and butchers.

I am, sir, yours, etc.,

A. L. CARROLL.

NEW BRIGHTON, Jan. 11, 1880.

THE SIZE OF BLOOD-CORPUSCLES.—A letter upon the above subject, from Surgeon J. J. Woodward, U. S. Army, will appear in our next issue.

ARMY AND NAVY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 11 to January 17, 1880.

TAYLOR, B. D., 1st Lieut and Asst. Surgeon. Assigned to temporary duty at Governor's Island, N. Y. H., as assistant to the attending surgeon at Div. and Dept. Headqrs., and to the Post Surgeon, Ft. Columbus. S. O. 7, Dept. of the East, Jan. 12, 1880.

Changes in the Medical Corps of the Navy during the week ending Jan. 17, 1880.

Asst. Surgeon W. G. G. WILSON to the Naval Hospital, New York, as the relief of Asst. Surgeon M. H. Crawford, detached and waiting orders.

Asst. Surgeon M. H. DRAKE, to the Naval Hospital, New York.

P. A. Surgeon D. O. LEWIS, detached from the Receiving Ship Independence, and ordered to the "Jamestown," at Alaska.

P. A. Surgeon, T. H. TEMPLE, ordered to the Receiving Ship Independence, Mare Island, Cal.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending January 17, 1880.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.—The next meeting of the State Medical Society will commence on Tuesday, February 3d, and continue till Thursday noon. It is hoped that opportunity will be afforded for crisp and thorough discussion of the material presented.

Papers or remarks have been promised from Doctors Potter, Batavia, on "Rectal Alimentation;" W. S. Ely, Rochester; John Vedder, Saugerties, "Hygiene;" E. M. Moon, Rochester, "Colles's Fracture;" Theo. Dimon, Auburn, "Necrology;" G. E. Benson, Hudson, "Ovariotomy;" Caleb Green, "Biographical Sketch of Dr. H. N. Eastman;" G. H. Fox, New York, "Vascular Nævus;" D. B. St. John Roosa, New York; J. C. Peters, New York, on "Prevention and Stamping Out of Certain Zymotic Diseases;" Elisha Harris, New York, on "The Domestic Pestilences: a Practical View of Etiological Facts, Medical Experience, and Public Health Duties in regard to Diphtheria, Scarlatina, Puerperal Fever, and Small-pox with Reference to the Sanitary War against them;" J. Marion Sims, "Thomas Keith and Ovariotomy;" Alex. Hutchinson, Brooklyn, "Forced Alimentation;" Lewis A. Sayre, New York, "Practical Demonstration of the Latest Improvements in the Treatment of Lateral Curvature;" Thos. R. Rooley, New York "After-treatment of Cataract;" W. C. Wey, Elmira

'Perityphlitis;" Fred. Hyde, Cortland. "Tapping the Abdomen;" John C. Shaw, Brooklyn. "Demonstration of the Pathological Anatomy of the Spinal Cord;" L. D. Bulkley, New York, "Management of Infantile Eczema;" A. Van Derveer, Albany, "Typhlitis and Perityphlitis;" B. L. Hovey, Rochester, "Fractures and Injuries of Knee-joint;" N. Nivison, Burdette, "Physiology of Opium-poisoning;" J. R. Leaming, New York, "Endemic Pleuro-pneumonia as appearing in New York for the Last Ten or Twelve Years;" C. C. Gay, Buffalo, "Refracture for Correction of Deformity;" J. W. S. Gouley, New York, "Cystorrhagia;" Jno. C. Dalton, New York; A. M. Phelps, Jefferson City, "New Treatment of Empyema;" Geo. F. Shrady, New York, "Subperiosteal Resection of Humerus, with Reproduction of the Bone;" E. N. Chapman, Brooklyn, "Mercurials in Congestion and Subacute Inflammation of the Stomach and Duodenum;" Jno. P. Gray, Utica; Alfred C. Post, New York, "Certain Unusual Deformities of Fingers and Toes;" F. R. Sturgis, New York, "Notes on So-called Galloping Syphilis."

Slow Pulse.—Dr. W. Hamilton Naylor, of this city, writes: "In a recent issue, I find a few cases relating to slow pulse mentioned.

"Rowell, the well-known pedestrian, had a normal pulse of 48, and no cardiac disease.

"During his two great feats of endurance in this city, when I was his professional adviser, I never found it to exceed 50, with one exception, viz., on the evening of his finishing his last race, when it indicated 52.

"At the time of his illness it fell to 22."

Editorial Change.—The term of four years having expired for which Prof. Wm. H. Byford was elected to the senior editorship of the *Chicago Medical Journal and Examiner*, he has declined a reappointment, and Dr. J. Nevins Hyde is now senior editor in his stead. Dr. Hyde is the man to fill the vacancy, and we congratulate him accordingly, or rather the *Chicago Medical Journal*.

The New York Pathological Society—Officers-Elect.—At the annual meeting of the Society, held January 14, 1880, the following officers were elected for the ensuing year: President, Dr. T. E. Satterthwaite; Vice-President, Dr. George L. Peabody; Secretary, Dr. George F. Shrady; Treasurer, Dr. J. H. Hinton; and Editor of Transactions of Society, Dr. John C. Peters.

The New York Academy of Medicine and the "Loving-Cup."—A beautiful and costly silver cup was presented to the Academy at its meeting, January 15th, on behalf of Mrs. John Jacob Astor, as a testimony of her respect and esteem for its Fellows, and with the hope, on stated occasions, "that it may procure a moment's pleasure to those whose days hold, necessarily, so large a measure of care and sacrifice." A full report of the proceedings will appear in our next issue.

The High Potency Question.—We quote from an article in the *American Observer*, a homœopathic journal, an endorsement of certain recent homœopathic investigations on the subject of high potencies: "Dr. Samuel Potter has very clearly shown, in his admirable and unanswerable argument, that chemistry is unable to furnish proof of the material presence of the medicine beyond the *third* attenuation; that the spectroscope gives no evidence beyond the *fifth*; the microscope, none beyond the *seventh*; and that the theory of molecular magnitudes (mathematical demonstration) stops at the *eleventh* centesimal dilution. Science, therefore, fails to demonstrate the possibility of the presence of the drug in any higher attenuation than the tenth or eleventh.

The Alkaline Theory of Yellow Fever.—In an addendum to the report of the yellow fever commission, published in the *National Health Bulletin*, Dr. Charles Finlay presents the following considerations to support the view of a probable connection between the prevalence of yellow fever epidemics and atmospheric alkalinity:

First. The high figures of atmospheric alkalinity in Havana coincide with the greatest intensity of yellow fever in that city.

Second. In the pathology of yellow fever it has been found by Dr. Blair, and since verified by other observers, that the blood, the breath, the perspiration, and the vomited matters (at certain periods of the disease) are markedly alkaline, owing to the presence of an excess of volatile alkali.

Third. Some of the most remarkable symptoms of yellow fever bear a strong analogy to those of gradual intoxication by volatile alkali, such as ammonia; *e. g.*, hemorrhagic tendency, scorbutic condition of the gums, albumen found (*post-mortem*) in the urine, gastric irritability, as observed by Dr. Richardson (on the coagulation of the blood), Christison (on poisons), Orfila, and others.

Fourth. The poison of yellow fever is considered by such an authority as Dr. Parkes to have existed in some cases in sewer-air, whereas Odling's observations show that the putrid substance in sewer water appears to be allied to the compound ammonias, and contains less carbon than ethylamine and more than methylamine, thus corroborating the conjecture that the yellow fever poison may itself consist in such a chemical compound, for the development of which an ammoniacal condition of the atmosphere may be considered as a highly predisposing, perhaps essential circumstance.

Fifth. Among the disinfectants recommended against the yellow fever infection, only acid substances are mentioned, and the most efficacious is believed to be nitrous acid fumes, as would also probably be the case in the supposition of a volatile alkali being the agent to be destroyed.

Sixth. Finally, the various empirical treatments practised in the West Indies by non-professionals have always had oily and acid substances for their foundation, just as if the object in view consisted in saponifying or neutralizing some alkaline poison introduced in the system.

Tetanus following Abortion.—Dr. W. G. Frost, of Danversport, Mass., writes: "I offer the history of the following case as one comparatively rare: I was called, June 18th, to see Mrs. S——, Irish, 35 years old, mother of twelve children, and found her nearly moribund from excessive hemorrhage attending an abortion at three months. By the use of the tampon, ergot, and stimulants, she rallied without difficulty. The next day she was very much improved, but absolutely refused to allow me to remove the tampon, or in any way to ascertain her condition. Argument, persuasion, and attempts to frighten availed nothing. The following day she told me everything was all right; but of this I had, and could obtain, no proof. Advising proper care, and rest in bed for a week, I left her. She was about the house the 21st; did the cooking for her family the 22d and

23d, and on the evening of the 24th I was called to see her. On the morning of the 25th the jaws were firmly set. During the day the whole body became rigid, and when raised by the shoulders she rested on her heels. She died on the morning of the 26th, exactly three days after her abortion. Her mind was clear to the last. Treatment availed nothing, as the chloric nately rejected everything but the mildest measures."

CHEMICAL ASSOCIATION.—At a recent meeting of the Philadelphia Academy of Natural Sciences, Dr. A. J. Parker stated that Dr. Mills had lately found, while examining the brain of a white person, that the central fissure ran completely into the Sylvian fissure, without any bridging convolution. This was the third record of such an occurrence, and had an important bearing upon the morphology of the convolutions. Bischoff's theory regarding the arrangement of the fissures and convolutions was criticised in this connection, and the opinion was expressed that the fissure of Rolando must be assigned to position with the frontals.

VIABILITY OF THE FŒTUS AFTER THE DEATH OF THE MOTHER.—Dr. Robert P. Harris, reviewing this subject in the *American Journal of Medical Sciences*, states that there are reasons for believing that, under some peculiar and exceptional circumstances in which the condition of the fœtus resembles, perhaps, that of hibernation, the life of the infant is prolonged in the womb of the dead woman for one or even two hours. Beyond this he is not prepared to go. A very large proportion of cases operated on five or ten minutes after the death of the mother will prove to be failures. Dr. Harris is of the opinion that the operation of Cæsarean section, for removal of the infant, is done in the United States much oftener than is supposed.

A CASE OF RECURRING FIBROID.—A case of "recurring fibroid," or, as it is now called, myxosarcoma, is related in the *New York Medical Journal* for December, and is interesting for the length of time during which the tumor lasted, and the number of operations which the patient underwent. The patient was born in 1822, and first noticed the growth in the back near the dorsal portion of the spine when he was 16 years old. It was first removed in 1839 by Dr. Knight, of New Haven, without, of course, the use of an anæsthetic. It was not entirely taken away, and the operation was performed again in about six months. Eight years later the tumor had recurred, and was evidently involving the spine, as partial paralysis was produced. It was removed, and the paralysis almost entirely disappeared. After this date the tumor reappeared, causing more or less paralysis, and was removed, with great relief to the same, about every five years. The patient was operated on, in all, twelve times, the last time with no relief. Two months after the last operation, in July, 1878, he suddenly became quite ill, and died with symptoms of acute pleurisy. On post-mortem the tumor was found to have invaded the pleural cavity, where it was the size of a double fist, and had set up an inflammation and effusion.

IMPROVED METHOD OF TREATING NEWLY-BORN CHILDREN.—Dr. W. J. Craigen, in the *Philadelphia Medical and Surgical Reporter*, relates his method of treating new-born children, which has some marked peculiarities. He says: "In my treatment of the infant it is not washed; it is not dressed; it is not fed; it is not bandaged; its umbilical cord is not compressed." He rightly remarks that this method may appear novel to the mass of physicians. He adopts it because he thinks that the prevalent treatment exposes the infant too soon to the cold, and brings about too sudden a change in its environment. Dr. C. rubs the child over with lard, wraps it in flannel, and does not have it washed for twenty-four or thirty-six hours.

REPORT ON PROGRESS OF THE ADOPTION OF THE METRIC SYSTEM.—The committee appointed by the Kings County Medical Society to examine into the movement to secure the general adoption of the metric system have made their report. They announce that during the past year the system has been endorsed and adopted by the New York State Medical Society, the New York County Medical Society, and the American Medical Association. The British Medical Association appointed a committee to report on the means of introducing the system into Great Britain. The Medical Section of the French Association for the Advancement of Science, and the International Medical Congress at Amsterdam, recommended the general adoption of the system.

The committee presented resolutions for the adoption of the system by the Kings County Medical Society. No action has yet been taken on the report.

WOOL-SORTER'S DISEASE.—A recent death from this disease, at Shipley, England, has called attention to what is still an obscure affection. It has been known for some time that workers in alpaca, mohair, camel's hair, and dry Eastern woods, are subject to sudden and often fatal attacks. In the case lately reported the man had complained for several days of the noxious character of the wool; he was finally taken with what was thought to be a severe cold; evidences of congestion of the lungs followed, and in four days he died. The cause of death in these cases is evidently some poisonous exhalation from the wool. Dr. Bell, of Bradford, England, who has had considerable experience in the disease, believes it due to living organisms from the fleeces of animals that have had anthrax. He states that it can be communicated from man to animals, and that myriads of bacteria (Bacillus anthracis) may be found in a drop of blood after death. The disease can be easily prevented by heating or steaming the wool.—*Lancet.*

THE ELECTRIC LIGHT PERFECTED.—There are various reasons, as we shall presently show, for causing the medical profession to take a deep interest in the progress of Mr. Thomas A. Edison's labors to perfect the electric light; and, in view of the conflicting opinions expressed by the daily press and some scientific authorities, we have taken steps to present our readers with a reliable statement of the actual results obtained by Mr. Edison, prepared by one of our staff, who made a personal investigation at Menlo Park on behalf of the MEDICAL RECORD.

The form of the new electric lamp is very simple, and can be well understood without diagram. It consists of a glass globe two inches in diameter, and a glass tube four inches long and one inch wide, tapering towards the bottom. The globe is attached to the top of the tube, which, in its turn, is fastened to a burner. The interior is also very simple and devoid of all mechanism. In the globe is seen a loop of paper carbon, the thickness of stout black cotton, supported by two metal standards.

To use the lamps, they are placed in little cups, which replace the gas nib on the chandeliers, and are dropped in as a glass stopper in a bottle. There is no trouble of tying wires, as it is so arranged that the act of placing the lamp in position at once con-

jects the lamp with the central station, where the electricity is generated.

This new form of electric light, as seen by us, burns with a steadiness which appears almost absolute. In four hours it was observed to make but one movement, which was instantaneous, and as new generators were used for the first time, which had never been tested, perhaps this single instance was caused by some change of the machinery at the central station.

Each lamp is arranged to give the same quantity of light as an ordinary gas-burner, but from our observation the illuminating effect was increased, due apparently to the great dispersive power of the light and its purity. All parts of the room are equally illuminated, and the general effect is that of a room lighted with a good supply of the best gas. With opal shades on the chandeliers, with the new electric light it would be barely possible to decide if gas was used or not.

When used without shades, and held within a yard of the face, it can be stared at for many minutes without any discomfort to the eye, and appears as grateful to that organ as the light of a wax candle.

Our investigation extended to viewing it as used for domestic purposes in Mr. Edison's house, where, in the parlor, two chandeliers with four burners were doing duty; also in a cottage, where one lamp illuminated a room about 12x16 feet. In the laboratory we saw it hitched on to conducting wires running in various directions, and in the factory and workshops as bracket lights. Lastly we observed it as an outdoor illumination, taking the place of gas in ordinary street-lamps.

In one word, the results were in all cases uniform and satisfactory, and the great blazing electric light, with which our minds associates that illumination, was seen toned down to the sober limits of an ordinary gas-jet, diffusing a soft and beautiful light of great dispersive power.

Thus Mr. Edison clearly demonstrated to us that he had solved the question of subdividing the electric light, and had produced an electric lamp suitable for domestic use. The equally important points of the permanency of the paper carbon and the ultimate cost of generating electricity still remain undecided. Experiments with the new electric lamp apparently lead to the conclusion that it is sufficiently permanent for practical purposes. Two lamps have been used, with short intervals, for fourteen days, burning day and night; one lamp was maintained for seven days and nights, with one interval only. We give full weight to the fact that the new electric lamp has been invented but a few weeks, and our surprise is great that it works so perfectly at the start. This appears to show that the principle is right, and if that is so, the rest will follow. We regard the item of cost as one of the least difficulties, because if steam produced by the combustion of coal is too expensive for generating electricity, the now wasted energy of tidal rivers and running streams may be available.

This, the last and most important of all Edison's discoveries, will be of the greatest benefit to the medical profession. By simply attaching a couple of wires to the chandelier, the new electric light may be placed in any position most convenient during clinical examinations; may be held in the hand in close proximity to the patient without fear of fire, heat, or unpleasant odor. The lamp may also be fixed to the back of a chair in any part of the room.

A motive power is also provided, always ready for use, and will be found convenient for many professional uses, and may lead to the introduction of new and valuable instruments and surgical appliances.

The hygienic value of the new electric light will be appreciated by those in charge of hospital wards and large establishments, in which a number of persons are congregated. The contamination of the atmosphere by sulphurous fumes of gas will no longer be feared, and, with moderate precautions and suitable ventilation, the air of hospital wards may be maintained in a pure and satisfactory condition.

Medical Charity and what Comes of It.—"Having, in a long time of practice, both from choice and necessity, done a great deal of gratuitous service, I have yet to find a single case where my charity work was appreciated. Those who pay nothing always offset it by liberal abuse, which keeps away those who would pay. Your charity ease may be a worthy man, but if you were making a struggle to build a house, would he work for you at reduced rates (or for nothing)? It is the doctors themselves, who allow their kind feelings to overrun their judgment, that are responsible for this wholesale robbing to which every doctor in this land is subjected. We deal with the most afflicted; so does the undertaker, who is not expected to work for nothing. We can maintain no rights that we weakly yield to extortion.

"The doctors are most universally regarded as rich persons who ride about for exercise, and practise for philanthropy, to be paid if everything turns out lovely; if not, they can go to the d—l and must not complain. The people who pay are always grateful; the thieves are like other dead-beats, abusive and always most exacting and querulous. . . . If the patient cannot pay for what might save his life, his friends or the public should. It is easier for the town to shoulder the cost than two or three poor devils who had the bad luck to study physic. Now or never is the time to put ourselves on the same footing with other businesses, and, as we have the same losses, we must ask for the same gains."—*Canada Lancet.*

The Cure of Consumption.—There seem to be grounds at last for hoping that a really effective curative agent against consumption in all its forms has been found. Professor Klebs, of Munich, some time ago, calling attention to the large number of internal diseases known to be caused by infection, classed among them tubercular diseases. Dr. Max Schneller, of Greifswald, being interested in the subject, tried several experiments, and having produced tuberculosis in two groups of rabbits, subjected one group to the ordinary treatment, and put the other for several hours daily "in a box filled with the vapor of a solution of what the Germans call 'benzöesaures Natron.'" The former group died, the latter recovered perfect health. Professor Rokitansky has since tried making his consumptives at Innsbrück inhale similar vapors daily. The results are said to have "far surpassed his hopes," and high medical authorities are of the opinion that at last a real advance has been made in solving one of the most important and difficult of modern medical problems.

Testing High Potencies.—At the meeting of the Homœopathic Association at Lake George, last summer, a member volunteered to prove the power of high dilutions by the following test: a number of bottles should be given him, all containing alcohol, and one in addition containing the fifteenth dilution of a certain drug. The doctor asserted that he could

tell which was the medicated bottle by its effects upon the system, and he agreed to undertake the experiment.

At a meeting of the Pharmaceutical Committee of the American Institute, it was voted that the doctor's proposal be accepted and the test made. A committee was appointed containing the names of such men as Dr. Chemeray and Professor Chandler. At the last moment, however, the courage of the experimenter failed him, and he sent word that the pressure of business would not allow him to attempt the experiment. The scientific world, therefore, still remains in a state of depressing uncertainty as to the physiological effects of the fifteenth dilution.

Mistaking a Traumatic Aneurism for Abscess.—A somewhat remarkable case has recently occurred in Chicago, and there attracted much attention. On about the 1st of October a young man, named John Conroy, was shot in the face. Dr. E. W. Lee was called in, and found a wound under the right eye. The patient's jaws were firmly locked; there was much pain and some fever, and swelling of the glands on the right side. The wound was not probed, but treatment was directed towards allaying the inflammation. The man gradually improved, and at the end of a week went out to his business. In another week he returned to Dr. Lee, much worse, and unable to speak or swallow. On examining the mouth, a tumor, the size of a hickory-nut, was felt on the hard palate. It felt hard. An exploratory incision was made, which let out some blood-clots, but no hemorrhage followed, and a free incision was then made in hopes of finding the bullet. Immediately, upon doing this there came more clots, and then a stream of bright arterial blood. An attempt was made to arrest the hemorrhage by filling the cavity with a piece of cloth; but the man struggled so violently that it was impossible; the blood issued from his mouth and nose, and he died immediately.

The post-mortem showed that the bullet had passed down to and pierced the internal carotid about three-quarters of an inch below the carotid foramen. A large cavity filled with blood-clots was connected with this opening.

When the case was brought before the coroner, Dr. Moses Gunn testified that Dr. Lee's treatment of the case was a perfectly proper one. Also that there was scarcely any possibility that the man could have lived long in any event. Dr. Fenger, who made the autopsy, testified still more positively than Dr. Gunn that the aneurism must within a few days have made a spontaneous opening, as pus had already appeared among the glands of its lower part. Drs. Dunne and Hobbs testified in the same way.

The jury rendered a verdict entirely exonerating Dr. Lee, and stating that under the circumstances he was perfectly justified in making his opening incision. This seems to have been the view generally expressed among the medical men. The friends of the deceased, however, have shown much excitement over the verdict, and have threatened both coroner and jury.

New Method of Preserving Dead Bodies.—The German government has recently bought the patent for a new preservative fluid. It is claimed for it that the bodies, even after years, retain their color, form, and flexibility. Decay is entirely prevented, and the muscles even keep their natural color.

The bodies are saturated in a liquid made as follows:

℞ Alum	100
Sodii chlorid	25
Potassii nitrat	12
Potassii carb	60
Acid. arsenici	10
Aquæ	1000

This solution is cooled and filtered. There are then added to ten litres of the fluid four litres of glycerine and one litre of methylic alcohol. From two to five litres of the liquid are used in saturating the body to be preserved.

Calomel vs. Hydrargyrum cum Creta.—I have been reading the communication of Mr. E. Merlett Boddy on the advantages of calomel as a remedy in some of the diseases of childhood. I write now a few lines to express my entire concurrence with the author in his disapproval of the well-known powder of mercury with chalk. As a means by which the system may be gradually saturated with mercury, small doses of mercury and chalk-powder are doubtless very effectual; but, as a cholagogue to induce secretion from the duodenum and liver, I believe a far more certain medicine is found in calomel. One grain of calomel triturated for some time with twelve grains of sugar of milk forms a very active cholagogue powder when administered in a dose of one or two grains. The well known blue-pill also may be dependel upon for cholagogue action, especially if the pill-mass be of some age, so that a small quantity of the suboxide of mercury has been developed in it. Metallic mercury, "killed" by minute trituration with sugar of milk, forms a gray powder that can be easily prepared in the same way as the hydrargyrum cum creta, and, so far as my experience goes, is a preferable medicine. Hydrargyrum cum magnesia I have also tried in one case, but have nothing special to report of its action. I give a decided preference to calomel and blue-pill as the best forms for obtaining the cholagogue action of mercury. The practice of frequently administering small doses of hydrargyrum cum creta with a view to correcting secretions is objectionable, as its tendency is gradually to impregnate the system with the mercury, and so produce irritability and anæmia.—*John C. Thorowgood in Medical Press and Circular.*

Sudden Death of Pilots. Two cases of sudden death of pilots, while at the wheel, have been recently reported. One was an officer on a Mississippi steamer; the other, pilot of the Union Ferry Company's ferry-boat *Fulton*. The cause of death in both cases was disease of the heart. These occurrences should make the people insist that there be two men in the wheel-houses, and that there be a physical examination of all the employees. This latter can be had without expense, by applying to U. S. Marine Hospital officers.

Royal Medical and Chirurgical Society's Library.—This society has recently finished a complete catalogue of its library, making a work of three large volumes. The library now contains 31,000 volumes. In the catalogue both authors and subjects are indexed—a peculiar feature being that the names of works are arranged in chronological order. —*Lancet.*

New Amphitheatre at La Salpêtrière.—Professor Charcot has had a new amphitheatre built at La Salpêtrière, and it was recently opened by himself. He delivered an eloquent address before an audience of over 500 students.

Original Lectures.

A CASE OF EXTRA-UTERINE FŒTATION,

A Clinical Lecture delivered at the Hospital of the University of Pennsylvania, Philadelphia.

By WILLIAM GOODELL, M.D.,

Professor of clinical and didactic gynæcology in the medical department of the university of pennsylvania.

(Reported for The Medical Record.)

I have to-day a case of exceeding interest and rarity—a woman presenting the phenomenon of extra-uterine fœtation. What do we understand by such a term? Extra-uterine fœtation is an error in the position of the fœtus, which develops outside of, instead of within the womb. There are probably three varieties of extra-uterine fœtation: (1) the *tubal*, in the Fallopian tubes; (2) the *ovarian*; and (3) the *abdominal* or *ventral*. Under the first head we have the (a) *tubo-ovarian* pregnancy, in which the germ is arrested in the pavilion which forms adhesions with the ovary; (b) the *tubo-abdominal*, in which the germ is also arrested in the pavilion which forms adhesions with neighboring abdominal organs; (c) the *tubal* proper, in which the germ is arrested between the pavilion and the uterus in the tube; and (d) the *tubo-uterine*, in which the ovum is arrested in that portion of the tube which traverses the uterine wall. Under the second head there is: (a) the *ovarian* proper, in which the germ is contained in the ovary, that organ remaining free from adhesions; and (b) the *ovario-tubal*, in which the ovary containing the germ contracts adhesions with the pavilion of the tube. Coming to the last head of *ventral* or *abdominal* pregnancy, we have the *primary* (in which the ovum is developed from the outset in the peritoneal cavity), and the *secondary* (in which the development commences in the tube or ovary, the cyst ruptures, the ovum escapes, and continues to live and develop in the peritoneal cavity).

The late Dr. John Parry thus classified 500 cases of extra-uterine pregnancy which he was able to collate:

Tubal.	The ovum being developed in the tube proper	149	214
	The ovum being developed in the pavilion: the tubo-ovarian and tubo-abdominal varieties	34	
	The ovum being developed in the uterine portion of the tube: "interstitial" or tubo-uterine pregnancy	31	
Ovarian			27
Abdominal (primary)			29
Doubtful			20

It is very easy to understand how an ovum may be impregnated in the ovary or in the Fallopian tube; but, when we come to consider abdominal pregnancy, it is not so plain. I have just spoken to you of two varieties of abdominal or ventral pregnancy, but must tell you that there is a question as to whether such a thing as a primary abdominal pregnancy is possible, *i. e.*, whether an ovum has ever dropped into the abdomen in the beginning, and formed adhesions there. The presumption is certainly against it, since there is no stroma for attachment; but, that such a thing both may occur and has occurred—in other words, that the ovum may fasten itself to the intestines or walls of the abdomen, though well-nigh incredible, would seem to be demonstrated by a few substantiating cases.

The great majority of extra-uterine gestations occur in the tube. Such cases are, as a rule, exceedingly fatal. The fœtus will possibly go on developing, and may reach its sixth or eighth week, when the physician is suddenly called in and finds the patient in a collapse, consequent upon a rupture of the tube from overstretching of its muscular fibres. I say that, as a general rule, tubal pregnancies are fatal; but, when the pregnancy is ventral, the woman will often go to full term.

The phenomena of extra-uterine pregnancy are peculiar, and yet the diagnosis is most difficult. About the first symptom with which we meet are colicky pains, which are likely to be excessively severe, and which are generally attributed by the patient to an effort at menstruation. These pains may be due to expansion of the tube or cyst. Sometimes they are almost as severe as the pains of peritonitis. Their cause does not seem to be well understood.

The next symptom is the arrest of menstruation. In this connection I may call your attention to the fact that membranes will be discharged from the womb which are likely to mislead the medical attendant into regarding the case as one of abortion. The growth of these membranes has been explained to be due to the fact that the jealous womb acts as if it were pregnant, and thus forms a false decidual membrane, which comes away in a hemorrhage or in the form of a sac. Later still there may be a second discharge—which the patient will tell you was a miscarriage—in the course of which a still greater amount of membrane may come away, either in bulk or in fragments. This second discharge generally means that the cyst is about to burst. Its cause remains a mystery.

The great ease with which the prominences of the fœtal body can be distinguished through the abdominal wall, the distinct placental bruit, and the tic-tac of the fœtal heart, are of great assistance in diagnosing these extra-uterine conceptions.

The causes of extra-uterine pregnancy, though obscure, would seem to be numerous. It sometimes occurs in women who have gone seven or eight years without conceiving. Why this is so, I am not able to say. Again, any obstruction, such as cancer, or a fibroid tumor, which prevents the passage of the ovum into the uterus, is set down by some as an occasional cause of the condition which we are discussing. Still other authorities assign emotional causes, such as the sudden opening of a door upon the act of illicit coition, or the influence of fright, or strong passion at, or near the time of coitus, when, as a result of a spasm, the ovum may escape into the abdomen. Extra-uterine pregnancy is occasionally a result of coition had during menstruation. Once or twice it has been known to follow pelvic peritonitis.

Some years ago a distinguished physician was attending a lady residing in West Philadelphia, for what he supposed to be an attack of pelvic cellulitis. Though the treatment pursued was vigorous, a month elapsed without any improvement in the symptoms. I was then called in consultation. I examined the patient carefully, and found the vagina tense and excessively tender to the touch. I diagnosed the case to be one of pelvic peritonitis. Two months more passed by, when the late Dr. Parry, who had also been called in, came to me and said, jokingly, "Doctor, you have made a bad blunder! The trouble is merely normal pregnancy." Nevertheless, I knew there was something *abnormal* in the case. I again visited the patient, and had barely begun my examination when suddenly it flashed upon me: "What

I have here is a case of extra uterine fœtation." I felt the head of the child bulging into the vagina. I suggested an operation, but the family objected. The child died shortly, and the mother perished. Here was an instance where three separate physicians were each and all of them deceived. Since then I have seen two other cases of the same character. One of these cases was a ventral fœtation to which Drs. Diner, Wallace, Parry, and myself were called in consultation. We made up our minds that an operation was the last thing that could be done; but the husband, who was devotedly attached to his wife, would not hear of our attempting it unless we would promise him that her life would be saved by it. This, of course, we could not do, and so the operation was not attempted, and the patient died.

This patient is a hunchback, who has been married three years. She is 30 years of age. I saw her first on the 7th of last October, and will read you an abstract of my notes taken at this visit. Two years ago she missed her catamenia for two months, and had a supposed miscarriage. She saw her last monthly in April last, which was normal in amount. On May 16th she had a slight flow, and then missed until the last of June, when she had a flow for a day, and lost a "piece of flesh" as large as an egg. From July 6th to July 12th she had a flow of black blood. Since then she has seen nothing. The introduction of the sound gives a measurement of four inches, and shows the womb to be in its natural position. To the left of the womb and closely adherent to it, is a large tumor filled with fluid and containing a solid body, movable by *ballottement*. The placental bruit can be heard distinctly on the left side. There is no milk in the woman's breasts, but the areolæ have darkened. The cervix uteri is small, but the os is soft. The patient has dysmenorrheal cramps every day, "as if her monthlies were coming on." The tumor alternately contracts and relaxes. The presence of muscular fibre would seem to point in the direction of a tubal pregnancy. But, as the patient is in her ninth month, such a condition would be very rare. If the pregnancy were ventral, we should not have any muscular fibres present, nor would we in the case of an ovarian pregnancy. I may be in error in regard to this point, but for the life of me I cannot see how it can be anything else than a tubal pregnancy. Still, I never saw a tubal pregnancy progress so far. To return to our history: when contracted, the upper margin of the tumor lies two fingers' breadth below the umbilicus.

November 4th.—No further changes have occurred, except that the woman's abdomen is larger in girth and her areolæ are darker.

December 4th. The womb is on a level with the umbilicus; the cervix is pushed backward by a tumor filling out the vagina. The sound gives a measurement of 3½ inches toward the sacrum. No heart-sound can be heard, but fœtal movements can be felt by me and by the woman.

Early in the present month the patient sent for me, and as the woman was living in a small room in a third story, back building, where there were no facilities for an operation, I had her moved to the wards of this hospital.

Her condition this morning is as follows: the placental bruit can be heard on the left side. The fœtal heart-sounds can be distinguished between the linea alba and the crest of the ilium. It looks exactly like a normal pregnancy, except that the cervix is very high up. Taking May 16th as the date of the conception, she ought to be confined on the 16th of next month. It is very hazardous to allow such cases to go to full term, for then a spurious labor sets in, and the child dies. Why this is so I cannot say, but I think it was the celebrated Avicenna who said that pregnancy went to nine months, and then "labor set in by the grace of God." The danger, of course, lies in the septic absorption following the death of the child.

I am examining the woman to-day, I find pronounced tenderness on both sides of the abdomen, but very little fluid present. The woman is fully eight months gone, but the size of the tumor is not that of an eight months' child. It only reaches a little above the umbilicus, whereas it ought to reach to the ensiform cartilage.

There are two points which strike me with particular force in my examination of the case: (1) That the cyst containing the fœtus has but very little water in it; and (2) that the child is unusually small. These conditions are generally present in all cases of extra-uterine fœtation.

I have gone over the case with great care, but we are all very liable to make mistakes. Indeed, the celebrated Dieffenbach once had a case which was brought to him by Dr. Busch of Vienna, who had diagnosed extra-uterine fœtation, and, in the presence of thirteen members of the hospital staff, Dieffenbach opened the abdomen to find *nothing*.

To try and preclude every possibility of mistake, I will introduce the sound and see what measurements it will give. I find the os higher up than is customary, not so soft and not so large as we usually find it in normal pregnancies. In front of the os I find a hard tumor, which is no doubt the head of the child.

I pass the sound, running the risk of rupturing the membranes, if any there are to rupture in the womb, and, dropping my hand as low as possible, get a measurement of four and a half inches. If there were a fœtus inside of the womb I should certainly have ruptured the membranes in the course of these manipulations. The womb is somewhat distorted, so that I cannot get its full length. I find that I cannot turn the sound in the womb, which I know I could do if the womb contained a bag of waters.

Let us look at the woman's breast. I was able to squeeze some milk out of one of them the other day. Yes, there is milk in both of them now. The follicles of the left breast seem to be somewhat enlarged.

The dysmenorrheal pains, which she complained so much of early in the course of the pregnancy, have been relieved. These pains are generally greatest when the fœtus is smallest.

What do I purpose doing? I would much rather wait and let the child die. In attempting Cæsarean section before the death of the child, there is great danger of hemorrhage from the placenta; there being no contractile tissue where the placenta is planted on the left abdominal wall, any effort to remove the placenta would certainly be followed by the death of the mother. But the mother is so anxious that the child should live that I have determined to perform the operation in a few days. I shall use Pacquelin's *thermo-cautère* in making the abdominal section. After I have removed the child I shall tie the cord, cut it and drop it into the abdominal cavity. I shall stitch the edges of the cyst to the edges of the abdominal wound and leave the placenta untouched. Though the danger to the woman, both from exhaustion and hemorrhage, will be great, I shall try to save two lives.

Although I have done everything to strengthen my

diagnosis and to remove all possibility of error from it, I am yet in some perplexity. Is it possibly not a case of extra-uterine pregnancy? My repeated examinations with the sound would seem to render this provoking alternative impossible. Still, there is so much muscular structure in the walls of this cyst that it cannot be other than a tubal pregnancy, and a tubal pregnancy is a very rare occurrence. My friend Dr. R. P. Harris, whom I have invited here to-day because he knows more about the subject than any living man, tells me that if it does so turn out, this will have been the *third case* on record in which a case of tubal pregnancy has gone to full term. Perhaps it is a case of double womb, or of a double-horned womb. I wish I could be positive about the fact. At any rate, my first incision next Sunday shall be an exploratory one.

NOTE.—A week later Dr. Goodell stated that, having become deeply impressed with the idea that the alternate expansion and contraction of the tumor meant unstriped muscular fibre—that is to say, uterine tissue—he had, very fortunately, concluded to await developments. His patient fell into labor four days later, and was delivered of a small living child *per vias naturales*. He afterwards very carefully examined the womb, and found it to be a *uterus bicornis*, or a two-horned womb. In one horn the ovum had developed; into the other he had passed his sound.

REMARKS UPON A CASE OF SIMPLE ANÆMIA, AND UPON ONE OF TUBERCULAR PHTHISIS,

WITH MODERATE CARDIAC HYPERTROPHY AND RECURRENT ATTACKS OF HÆMOPTYSIS.

BY BEVERLEY ROBINSON, M.D.,

LECTURER UPON CLINICAL MEDICINE AT THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

GENTLEMEN:—The first case I shall bring before you to-day is not so interesting as I had reason to believe ten days ago; still, as even the most simple cases are sometimes the most instructive, so I am encouraged to make remarks about what is an instance of profound simple anæmia, which appeared to me, I confess, when I requested this patient to come here, an example of progressive pernicious anæmia. An abstract of this girl's case reads as follows: L. K., seventeen years of age, seamstress, residing in New York City, complains of breathlessness upon the slightest physical exertion. She suffers constantly from vague pains in her chest and from severe headache. Her appetite is capricious; sometimes she eats tolerably well, and again she does not care for her meals. She has no ambition to go through with her daily tasks, but simply feels unable to do any work at all. Formerly she had a healthy color and her cheeks were rosy. During the past two months she has been constantly ailing, and is always inclined to sleep. Her lips are blue, and every one says she looks as if she had no blood in her veins. For several weeks past her face has had a swollen appearance. After eating, she is distressed at times with nausea. Her bowels are regular, with a tendency to constipation. She is extremely nervous, and any sudden noise or shock affects her most disagreeably. She has painful palpitations at the heart. Hitherto her menstrual discharge has been sufficient in quantity, and during her monthly periods she has been free from pain. She has never remarked any leucorrhœa. In her previous history I do not find any proof of malarial poisoning. She is well fed, lives in a healthy locality, and her daily work is not excessive. Her mother and father enjoy excellent health, and so do her brother (nine years) and sister (five years). This patient presents no localized œdema in any region, according to her own affirmation. When I come to make a careful search I find evident pitting and pressure over the malleoli. Her urine is pale in color, does not give any deposit upon standing twenty-four hours, has a slight acid reaction, a specific gravity of 1008, and, by the ordinary tests with heat and nitric acid, does not show cloudiness due to the presence of albumen. Of this urine my patient passes seventy-two ounces in twenty-four hours. Upon physical examination, I find no enlarged lymphatic ganglia either in the groins, axillæ, neck, or elsewhere. There is slight increase of size in the spleen, as shown by the extent of dulness on percussion. The liver remains within normal limits. Under the microscope the blood presented the following characters: there was decided diminution of the number of red corpuscles, which were also very light in color. Their outline was distinct and rounded, and they hung together like pieces of money. The white globules were certainly more numerous in the field of the microscope than is normal, and they were smaller than usual. My patient has never had hemorrhage from any organ. I prescribed for her January 5, 1880, as follows:

℞. Fl. extract. cascara sagrada.

S. ʒss. in a little sweetened water at bedtime, and again in the morning, if required.

℞. Pil. ferrei carb. (Vallet).

S. One three times a day, with her meals.

Now, permit me to ask what the nature of this case really is. Is it anæmia of simple type, chlorosis, leukhæmia, or an example of that singular affection, described more especially by Biermer and Gusserow in latter years under the name of progressive pernicious anæmia?

I believe we fairly exclude kidney disease by the result of the examination of the urine. There is no albumen at present to be revealed by the ordinary tests, and as the patient has not had pain in her loins, and no other symptoms which cannot fairly be accounted for by the condition of her blood, I believe we can properly eliminate it from the discussion. How about progressive pernicious anæmia? Well, I am free to admit that I had a half-formed conviction, when I first saw this patient, she was an instance of this affection. She was so very pale, she was growing weaker each day, her heart was evidently not revivified as it should be by blood with healthy elements, and over its region there was heard an intense blowing murmur, which was most accentuated at the apex. There was already evident subcutaneous infiltration of cellular tissue over the ankles, and although hitherto there had been no hemorrhage, still the constitution of the blood seemed to render it of highly probable occurrence at any time. Unfortunately for the truth of this hastily formed judgment, my patient returns to me after only ten days' interval, and is already feeling notably better by reason of the administration of carbonate of iron pills. Now, as you all possibly know, one of the means of diagnosticating so-called progressive pernicious anæmia is through the touchstone of treatment. If treatment succeeds at all, we must abandon our diagnosis, for the onward tendency, or rather march towards a fatal termination of this disease is thus obviously interfered with. But does such reasoning hold good of chlorosis or leukhæmia? Certainly not of the first; for frequently, even in intense chlorosis,

we notice rapid and marked improvement of the chlorotic condition when iron is given for a week or two. But I can scarcely admit the existence of chlorosis, properly speaking, in this girl's case: first, because there has been no menstrual difficulty; second, because her aspect has never been precisely that of chlorosis. There has been no greenish or waxy appearance, but only excessive pallor. It is true that my patient has never been notably thin, or lost flesh to any considerable degree, but, on the contrary, is quite plump. This is an aspect which we may expect to see frequently, even with marked blood dyscrasia, and is no absolute index of the good or ill health of the patient. I submit, however, that my patient has a swollen aspect of the face, puffy hands, and pitting over the malleoli—all of which show conclusively a watery and imperfect state of the nutrient fluid. Finally, has my patient true or pseudo leukhæmia? In the absence of notably enlarged spleen, of lymphatic ganglia abnormally increased in size, of tenderness over the bones of the vertebræ or limbs, I believe we may assume that it is at least doubtful. Moreover, the rough examination made by me of the blood does not settle the exact condition of that fluid. The hæmatocimetro should be employed, and the number of white and red corpuscles in a given field accurately determined. Doubtless many errors arise in this and like observations from a want of precision or exactness. There may be an apparent, or even a relative excess of white globules in the composition of the blood, and yet this appearance or fact may be due simply to the decreased number of red corpuscles present in this same fluid. It is very necessary, therefore, to make exact microscopical investigations in analogous cases; or, at all events, if the microscope be lacking, to see what the test-tube can reveal when a given quantity of blood is poured into it, allowed to stand for some hours, and then the relative volumes of red and white corpuscles and other constituents of the blood are, in a manner, determined with an approximation of accuracy.

One word before leaving this case—and that is in regard to the intensity and location of the heart-murmur. The cardiac murmur is heard at the first sound all over the precordial region, but it is especially well heard—that is to say, it is most intense—at the apex. I am satisfied that it is a functional murmur—or better, a murmur brought on by the condition of the blood; and I base my belief mainly in this instance upon the fact that there is nothing in the previous history of this patient which will justify the supposition of an organic affection of the cardiac valves or orifices. And here I wish to make a profession of faith. There are a few well-known clinical observers—and in this class, among the most distinguished ones, we find Parrot—who believe that anæmic or dynamic murmurs are at times heard with greater intensity at the apex, and not at the base of the heart, as is usually taught in our text-books. Now, I am inclined to believe that this opinion is correct. For several years past I have listened with great care, when too frequent occasions have presented themselves, not only to the hearts of patients who, though anæmic, had not latterly gone through a severe illness, but also to hearts whose vital power had been put to the test by a severe attack of acute rheumatism or other febrile disease; and in these instances I have occasionally remarked that the region of most intense transmitted cardiac sounds was the apex, and not the base. How is this explained? It is presumed that in many such instances there is a temporary dilatation of the tricuspid or mitral orifice, occasioned by a relaxed cardiac fibre, which has allowed regurgitation to take place synchronously with every systolic impulse. A certain number of autopsies would also seem to corroborate the truth of this impression. To my own mind, it is a probable hypothesis. Many a man, I am convinced, is convicted by his attending physician of carrying in his breast a ceaseless and incurable cardiac murmur, who, in the future, gets entirely rid of it. And this is true, because in instances in which valvular thickening, or puckering, or calcareous deposits in the valves or on the margin of the orifices have been learnedly determined, there in reality existed nothing more serious than relaxation of muscular tissue and slight decline of normal nerve-force. Lay these truths well to heart, and in anæmia, chlorosis, etc., as well as during the continuance of, or convalescence from, severe forms of acute febrile disease (rheumatism, measles, scarlet fever, etc.), do not be too prone to recognize the existence of endocardial murmurs, which are sure to persist forever in future.

My other case is a doubtful one, at least in so far as the cause of moderate hæmoptysis is concerned.

Here is briefly his narrative: J. H., seventeen years old; printer; born and resides in New York City. On January 9, 1880, he came under my care, and told me that a short time before seeing me he had spat up a moderate amount of red, fluid blood, rather foamy, and during an attack of cough. About three weeks previous he had had a similar hemorrhage, in which he spat up about one teacupful of pure blood. During three or four days after this first attack of hæmoptysis he continued to expectorate, at short intervals, a quantity of viscid, thick sputa, streaked with blood, which was of dark color. Prior to these two attacks he never had spat any blood. He has had a frequently recurring dry cough for two years past, with moderate expectoration. His sputa are whitish and occasionally yellow. He has had, during the last few weeks, hot, abundant perspiration during the night, but has become, in great measure, relieved of his cough. Since last summer he has lost notably in flesh, but his strength remains as usual. He has suffered latterly from stitching pains in different regions of his chest, and since he had his last attack of hæmoptysis he hears distinctly certain whistling and moist sounds during respiration, that he attributes to the passing to and fro of air through blood in his bronchial tubes. This young man is well fed, clothed, and lodged. He is continued ten hours in the twenty-four to the work of his trade. This work consists mainly in pulling the arm or lever of a printing-press with his right hand and arm, which are, of course, severely tested and frequently much fatigued. His father died at twenty-five years, but he does not know what the nature of his disease was. His mother is healthy, and is now thirty-five years old. A brother died of acute rheumatism. His only sister is grown, and enjoys good health. Some weeks ago he consulted a practitioner in this city, who informed him that he had an enlarged heart, and that he should abstain from his present active employment, and give himself a rest for a time. The patient doubts, as he remarks, the existence of any cardiac affection, because he has never suffered with his heart, never has had short breath or cardiac palpitations, and can even now run several blocks without feeling any unpleasant effects from this exertion. Moreover, upon questioning him I find there is no history of rheumatism, chorea, scarlet fever, malarial

poisoning, or, in fact, any disease which, either directly or indirectly, would be likely to give him organic disease of the heart.

Physical examination, unfortunately, not only reveals interrupted or wavy inspiratory murmurs at both apices in front, with markedly increased vocal resonance and fremitus under the right clavicle, but also a few disseminated moist râles, of medium size, over the entire area of both sides of the chest posteriorly. Besides, throughout this whole region there is augmented vocal reverberation during speech. There is, without question, some enlargement of the heart, particularly affecting the left ventricle. The apex-beat is just behind the sixth rib, but is carried considerably toward the left or outside of a vertical line passing through the left nipple. There are no cardiac murmurs, but there are feebleness and irregularity of cardiac action.

In this instance I believe there can be little doubt as to the existence of the first stage of tubercular disease of the lung. No more do I believe there can be reasonable suspicion that the diagnosis of moderate cardiac hypertrophy is not justified. But what is of interest for us to determine at present is, whether the recurring hæmoptysis be due to the incipient lung trouble or to the enlarged heart. It would seem, perhaps, at first, as though we should attribute the hemorrhage to the phthisical state, in view of its physical characters—the fact of its occurring during cough, and the presence of general symptoms which point to this interpretation as the correct one (night-sweats, emaciation, dry cough, etc.). Still, there is something to be said on the other side. The mere color of the blood cannot determine the question, because we may have a localized pulmonary congestion brought on by over-action of the heart, which would cause sanguineous expectoration, and the blood spat up under these circumstances might be very red in color. The fact even of its occurring during cough is not an absolute proof that the blood comes from a phthisical condition, because whatever blood there be in the bronchial tubes or lung-tissue, and whatever be the efficient cause of its presence there, nevertheless, in order that it be thrown off from the chest, it must almost of necessity come up during or after cough. Of course I know that mere hypertrophy of the heart, moderate in extent, and without recognizable valvular lesion, is a rare cause of hæmoptysis. But the rather immoderate physical exertion to which this boy is daily subjected, taken with his impaired nutrition and phthisical condition, would not require any very powerful additional exciting cause to set up a localized or more diffuse congestion of pulmonary structure. Evidently, if the hemorrhage is occasioned wholly by the phthisical condition, it is that sort which is due to congestion about a conglomeration of miliary tubercles, or else what Michel Péter calls "paraphymic" congestion, or one which is vicarious, and only occurs in the somewhat remote neighborhood of the existing tubercles. Certainly there is no reason, rational or physical, to dread the existence of a lung cavity, or of one of those profuse hemorrhages which are due to the ulceration of a vessel of large calibre in hard, non-elastic cheesy tissue. Rational therapeutics has a word to say in this place. Of course I shall keep this boy on an emulsion of cod-liver oil, and I will also deem it indicated to place repeated fly-blisters under his clavicles to diminish localized congestion, due to whatever cause it may be.

But what shall I say of other indications? In the doubt where I am, for the while I shall interdict the continuance of his trade, in which so much physical exertion is required, because, while I believe it has been a sufficient cause to produce his actual cardiac hypertrophy, so I believe it will aid by stimulating the heart to increased action, the occasion of augmented vascular tension in the lungs, as elsewhere, and thus infallibly lead again to hæmoptysis of more or less quantity. I shall, after a similar indication, advise regular habits, restraint from over-muscular exercise of any and all descriptions, denial of all stimulants, such as tea, coffee, and alcohol. This boy should live a great deal in the open air, and eat abundantly of azotized food.

One word more, and I have done. He says the doctor who first saw him advised him to take ten or fifteen drops of tincture of iron in water whenever he began to spit up blood. Shall he follow out this prescription? Of course you know, gentlemen, the iron is here given for its supposed styptic properties, or power of contracting tissues or blood-vessels. But there is one objection to its use which has been urged, with how much justice I can scarcely affirm—*i. e.*, that it predisposes to renewed hemorrhage by increasing localized congestion. I believe Trousseau taught this. I may, however, be mistaken. At all events, I would say that, individually, I have had the best results in arresting hemorrhage in cases more or less similar to this one, by giving internally the fluid extract of ergot, in frequently repeated doses, anywhere from ten drops to one drachm at a time.

ARTICULAR OSTEITIS OF THE KNEE IN CHILDREN.

NOTES ON ITS PATHOLOGY AND DIAGNOSIS, BASED UPON AN ANALYSIS OF THIRTY CASES.

BY JOHN JAMES BERRY, M.D.,

HOSPITAL FOR THE RUPTURED AND CRIPPLED, NEW YORK.

DISEASES involving or approximating the knee-joint, by reason of their frequent occurrence and tendency to assume a chronic form, have proven of especial interest to many whose office it is to check or mitigate their course. For this reason, we venture to offer some conclusions derived from an analysis of a considerable number of cases, of which the following are types.

To one appreciating the many conflicting theories regarding the location, character, and course of this and other similar inflammations, it is a matter of no little difficulty at times to arrive at a correct diagnosis of their nature; especially is this the case if he be without opportunities of making local explorations of the parts diseased. Thus it may be desirable to review briefly some of the phenomena manifesting themselves during the progress of the affection.

Formerly, this type of bone disease, which is known by Virchow as scrofulous osteomyelitis, and by Nélaton as tubercular osteitis, was not so fully recognized as an etiological factor in chronic articular inflammations—most authorities locating the primary changes in the synovial membrane, and denying that central disease of the bones invaded the structures of the joint itself; for, under the term "white swelling" was classed a great variety of degenerations,

such decidedly from the other as regards its pathology and results. This view as to its origin is likewise shared by some modern pathologists. Billroth, in describing the caseous synovitis, or, as he terms it, fungous disease of the joints, which he considers the most common variety of caries occurring in strumous children, describes the initial changes as taking place in the synovial membrane, and subsequently extending into the articular extremity of the bones, at the same time implying that a primary bone lesion is of rather infrequent occurrence. In opposition to this view, however, Volkmann,* Schüller,† and others, who, for a number of years, have been investigating this subject very carefully and conscientiously by the examination of many fresh specimens of excised bone, prove conclusively that not only is the tuberculous form of degeneration the most frequently met with, but that the latter is almost invariably located primarily in the epiphysis of the bone, but very subsequently, by an ulcerative process, involve the articular cartilage and capsular membrane of the joint; or, what is less frequently the case, the suppuration in the epiphysis, instead of progressing toward the articular cartilage, directs its course outward and away from the joint—and finally, creating a chronic inflammation of the overlying periosteum, originates a series of destructive processes in the tissues surrounding the femur or other bones entering into the formation of this structure. For, from the intimate relation existing between the periosteum and the epiphysis in children, as well as from the increased vascularity of the same portion of the femur, it is easy to explain the facility with which inflammatory processes external to the joint might assume a more serious aspect.

Again, cases are sometimes observed in which the inflammation has been arrested *in loco*, and the products of the same have either become encapsulated or absorbed, more healthy granulations filling up the excavation which would otherwise remain; these changes leaving at times little expansion of the bones, or serious impairment of the functions of the limb.

The experiments performed by these investigators, although confined to animals, are in other respects important and instructive contributions to the study of the disease. The results obtained have also shown that even slight injuries to the joints of animals who have previously been infected with tubercular virus, have caused the appearance of minute points of degeneration, almost invariably situated in the osseous structure, which microscopically have presented all the characteristics of miliary tubercle, and which, by their tendency to undergo caseation and subsequent softening, act as etiological factors in true joint disease. Volkmann is so impressed by the experiments made, that he is led to doubt the existence of any form of chronic articular degeneration other than the tubercular.

These destructive processes are similarly located by Le Sègue,‡ Duplay, and Macnamara,§ though they incline to the belief that the starting-point of the disease is either between or at the junction of the epiphysis and diaphysis of the bone affected, which is usually the femur, though the tibia is occasionally attacked in this manner.

In some of the cases illustrating this variety of disease, the morbid changes result in the formation of pus, which manifests itself quite late in the course of the affection, and is observed to occur external to the joint, usually just above the condyles of the femur—the tumor subsequently dissecting its course upward, between the tissues of the thigh, often as high as its upper third. As a rule, it gradually increases in size, and if not evacuated by incision, discharges its contents spontaneously, though it is not unusual for resolution and absorption to occur under the influence of firm and continuous pressure after the presence of fluctuation has proved the existence of a considerable quantity of fluid. The constitutional disturbance existing in such cases is usually insignificant, unless evacuation of the cavity of the abscess occur.

Associated with these processes in and about the extremity of the femur there is frequently a subacute inflammation, progressing within the cavity of the neighboring joint, its natural movements become more and more limited, there is pain thereabouts, and tenderness over the patella and lateral ligaments, with reflex contraction of the hamstring muscles which approximate the limb more or less completely to a right angle. In other cases, the inflammation, especially if it be the result of osteitic disease, which has made its destructive inroads into the joint and lighted up an acute degeneration there, is of a more destructive nature, and causes disintegration of the articular structures. This, however, is a process of many months' duration; for, owing to the peculiar anatomical formation of the extremity of the bones, there is a great resistance to inflammatory action progressing from the synovial membrane outward toward the osseous portion of the femur or tibia. It is, perhaps, unnecessary to state that this destruction of tissue is usually, if not invariably, secondary—it never having been observed in any case of our own, or of others with whom communication has been held. Smith,¶ of Philadelphia, who has published an instructive contribution to this subject, concludes that tubercular degeneration always originates in the bony structure. Cases are not infrequently observed in which those symptoms we have been taught to consider characteristic of chronic joint disease are almost entirely absent. There are no prodromata—no manifestation of tissue-changes—no grave constitutional results; in fact, it is at times a matter of no little difficulty to determine at exactly what period the inflammation ceases to be progressive.

The following clinical notes may serve to illustrate the several types of articular osteitis which have been observed:

Case VIII. Thomas D——, a healthy-looking and fairly nourished boy of twelve years, presented himself in November, 1879, at this hospital, for the purpose of obtaining relief from an affection of the right knee. There was no positive history of hereditary taint or predisposition to joint disease, though his father was said to have been subject to a slight idiopathic enlargement of the left knee. The initial symptoms date back about nine years, when, from no apparent cause, slight difficulty in running was experienced, though the act of walking was attended by no inconvenience. About two years subsequently there were added to this symptom those of stiffness and pain; the former slight, and observed only in the morning upon rising; the latter moderate in degree, and of no greater severity by night than by day, there being

¶ On Certain Points in the Pathology of Bones, especially Tubercle. Phila., 1878.

at times complete immunity from it. These manifestations have not increased in severity or degree since this time. The patient stands with the feet squarely on the floor, the weight of the body being sustained principally by the left limb. He walks with a slight limp, but freely and with comparative ease. The muscles of the affected side are considerably wasted—measurements showing two and a half inches atrophy. The electrical examination shows that the muscles of the left side respond with fully one-third their normal intensity. The knee-joint is much increased in size, as the recorded measurements indicate. Circumference of left limb one inch above patella, 10.5 inches; over patella, 12.5 inches; below latter, 9.5 inches. Right knee at corresponding points, 10 inches, 10.5 inches, 9 inches. There is no infiltration of the soft parts, the increase in size being evidently due to expansion of the extremity of the femur, though most of the hypertrophy seems to be confined to the inner condyle, which is not only enlarged circumferentially, but is elongated one inch by careful measurement. The tibia and fibula are partially subluxated and rotated outward on their axes over an arc of about ten degrees. There is no appreciable amount of fluid within the synovial capsule. The hamstring muscles are somewhat tense, but not much shortened. The limb can be passively flexed to an angle of 100°, and extended to an angle of 175°; but beyond these points motion is attended by pain and resistance. Concussion of the joint elicits no pain; neither is there any grating appreciable on movement of the limb. Excepting a slight increase of the surface temperature, there are no signs of acute inflammation.

Case XV.—Sarah B——, æt. 3, was brought to the Out-door Department Nov. 28, 1879, suffering from a chronic disease of the left knee-joint. No positive history of hereditary disease could be elicited. The mother of the child stated that the latter was perfectly well during early infancy, and remained thus up to the age of sixteen months, when she fell upon the floor, at which time she was supposed to have injured the knee, though no symptoms supervened to confirm this suspicion.

A few weeks subsequently, a small, circumscribed tumor appeared over the head of the tibia, which increased in size very gradually and without any marked symptoms, save some stiffness of the limb and enlargement of the joint. One year ago this swelling, which proved to be an abscess, opened spontaneously, discharging a considerable quantity of pus and leaving a sinus which has ever since remained open. Since rupture of the abscess walls took place, the general health of the child has become considerably impaired—she having experienced more or less elevation of temperature evenings, associated with extreme restlessness and insomnia. During the past year there have been frequent exacerbations in the disease, which were commonly quite marked in their character; for whenever the discharge from the sinus has become impeded, or arrested from any cause, the joint has become invariably tense, painful, and much enlarged, rendering movement almost impossible at times.

An examination, made at the present date, shows the patient to be fairly nourished and quite healthy in appearance. She stands squarely on the floor, resting the weight of the body equally on both limbs; she walks with a limp, but quite freely. There is a very appreciable amount of infiltration about the knee, as well as tenderness on pressure over its entire surface. The head of the tibia is somewhat enlarged, and there is situated over it a large cicatrix, adherent to the tissues beneath, and the site of a discharging sinus which leads down to carious bone. Both condyles are enlarged, the inner being three-eighths of an inch the longer. The joint appears tense and fluctuating, and the overlying integument is hot and reddened. Firm and continued pressure over the joint causes an exudation of pus from the sinus above-mentioned. The patella is in its normal position, is freely movable, and seems to float upon fluid of some kind. Extension of the limb can be passively made to the extreme normal limit, and flexion to a right angle without pain; motion at the joint is free and smooth to these limits—no grating or other abnormal sensation being experienced. The responses to the faradic current are diminished about one-fourth in the affected limb. There is no contraction of the hamstring muscles, and no atrophy of the thigh or calf. Circumference of limb above patella of left side, 8.8 inches; over patella and around condyles, 8.8 inches; below patella, 7.8 inches. Corresponding points on right limb, 9.5 in., 10 in., 8.5 in. During the last few weeks the health of the child has become somewhat impaired.

Case XXI.—Frank R——, æt. 4 years, was admitted to this hospital December 19, 1878. He was said to have been perfectly healthy previous to the inception of the present disease, which was first noticed in the preceding July. No hereditary taint discoverable, neither was there present any chronic disease in his family. At this date, the mother of the child noticed that he walked with a slight limp, which was associated with some pain and swelling of the knee. After a period of two weeks, however, these symptoms almost entirely disappeared, and the child again ran about with perfect ease. About one month later the joint began to be slightly stiff mornings, and to be the seat of considerable pain, which interfered somewhat with locomotion; these symptoms, however, would pass away in a few hours, and he would appear as well as ever. He was soon after taken to a dispensary, where a straight posterior splint was applied to the limb, which afforded him considerable relief—there being no distinct or positive symptoms complained of for some time afterward.

Two months previous to his admission, the apparatus was removed for the relief of the excoriations which it had produced; subsequent to this time, he has been totally unable to walk, and has suffered from continuous pain and extreme restlessness at night.

On examination, the boy is found to be fairly nourished, though rather strumous in appearance. He stands with the left lower extremity semiflexed at the hip and knee, the foot being thereby elevated a little from the floor. He refuses to walk, seemingly on account of pain about the joint; the latter is considerably enlarged around and above the condyles, due in part to infiltration, but presents no signs of acute inflammation, though the surface temperature is a little elevated. The patella is non-adherent, and movable over a small area. There is apparently little fluid within the joint. The condyles and overlying tissues are increased in size, as shown by the following measurements: Circumference of right limb an inch above patella, 8.3 in.; over patella, and around condyles, 9 in.; below patella, 7.5 in.; corresponding points on left limb, 9.3 in., 10 in., 7.6 in. The left thigh is an inch smaller than its fellow. The internal condyle shows the greater degree of enlargement, as herewith indicated. Outer lateral

sent circumference, 4.4 in.; inner side, 4.6 in. The length of the left femur exceeds that of the right by half an inch. The limb can be extended to an angle of 160 deg., and flexed over an arc of 30 deg. with ease; these movements are quite free, and associated with no pain, grating, or other signs of synovial degeneration. Consumption of the joint elicits no marked pain. No signs of former or present abscess apparent.

In addition to appropriate constitutional treatment, the knee is firmly compressed by a laced bandage, and extension and fixation of the limb favored by the apparatus employed by Dr. Knight for this purpose.

Oct. 22, 1879.—For the past few weeks he has become quite restless at night, and he has been noticed to cry out in his sleep. The joint is a little more tender and swollen than before. This morning the knee is found to be rigidly flexed at an angle of 135 degrees; the slightest motion, whether voluntary or passive, causes severe pain. The parts are very tender, and present a considerable elevation of temperature.

The capsule of the joint is much distended, as the following figures indicate: Circumference of limb above patella, 10.3 in.; over condyles, 11.3 in.; below patella, 8.8 inches. Constitutional disturbance not marked in character.

Nov. 10, 1879.—There has been much improvement in the boy's general health since the date of the last note, as well as in the condition of his knee, which appears also very much better in every respect. The arc of motion is now about the same as it was on his admission.

The following history illustrates the chronicity and slow progression so often exhibited by the affection, as well as the ultimate result obtained:

Case XXX.—T. M——, aged 7 years, was admitted to the Out-door Department of the hospital, August, 1876. Although he and his parents have always lived under bad hygienic influences, the histories of both, so far as could be ascertained, showed no hereditary predisposition to disease. His sickness manifested itself two years ago, from no apparent cause, by some trouble at the knee-joint, which began very insidiously and gave him little inconvenience; he walked with a slight limp, but complained of no pain or tenderness anywhere. Subsequently, however, they were present in a marked degree, and were associated with swelling and infiltration of the parts. Suppuration finally ensued, and a spontaneous evacuation took place. Since that time his health has been somewhat impaired, and for some weeks locomotion without assistance has been impossible. An examination made at this time shows that the boy is quite well nourished, though somewhat anæmic. He stands with the right limb semiflexed and advanced—the toes being elevated some inches from the floor. He is totally unable to walk without support—any use of the joint being accompanied by excruciating pain. The right thigh and leg are found, on measurement, to be a little atrophied. The normal contour of the knee is effaced by infiltration and enlargement. The patella is in its proper position, but immovable. The inner condyle is enlarged, but the heads of the tibia and fibula are about normal in size, though subluxated backward a little. There is some tenderness over the internal lateral ligament, but none elsewhere; surface temperature a little elevated. Extension of the limb can be passively made to an angle of 155 deg. and flexion to an angle of 90 deg. without the slightest pain. No grating or laxity of the ligaments appreciable. Concussion of the joint elicits some pain, which is not marked, however.

July, 1879.—Discharged this date very much relieved, though the maximum amount of improvement seemed to have been afforded some months previously. His general health is excellent. He stands squarely on both feet, and favoring neither side. He walks freely, but with a considerable limp, due to the flexed position of the leg. There is still a little displacement of the tibia and fibula. No pain or tenderness about the joint. Angle of greatest extension, 165 degs. Still wears apparatus.

October, 1879.—Returns to report his condition. There has been no relapse since his discharge. Angle of extension 170 deg. On careful measurement of the femora, the right is found to be three-fourths of an inch the longer. Electrical reaction good in proportion to the size of the muscles. Can walk long distances with ease. Apparatus removed. It may not be devoid of interest to notice briefly some of the prominent points relating to this variety of bone disease. The location of the pain and swelling is of some importance in this point of view; in most cases it is first found to be, not in the synovial membrane or in intimate relation with the joint cavity, but above and around the condyles, or over the head of the tibia, at which points the other signs of inflammation are also present. With a very few exceptions, the character of the pain differs in no particular from that attending other forms of bone degeneration—the sharp and sudden nocturnal cry being commonly absent, although the assertions of some observers as to its almost invariable existence, have led to its acceptance as a diagnostic sign by many surgeons.

From the location of the initial symptoms, therefore, it is improbable that the disease occurred primarily in the synovial membrane. The progress of the affection as well is no less characterized by symptoms of osteitic disease—the parents of the child commonly stating that while in good health, and under provocation apparently too insignificant to produce other than superficial injury to the parts, the child began to walk with a slight limp; to complain mornings of pain and stiffness at the knee; to resist passive motion of the joint, and to experience spasmodic contraction of the hamstring muscles; for, as we reflect upon the intimate relation existing between the nerves of the joint and the muscles associated therewith, we can scarcely expect other than reflex phenomena of an exaggerated form. That symptoms of synovial disease usually show themselves at some period during the course of the inflammation, is not denied; for it must happen at some time in its progress, provided its normal course and character be not otherwise affected, that those structures intimately connected with the articulation will have become involved. Neither is it questioned that the initial joint lesion is sometimes found to be situated in the synovial membrane.

In adults, destructive changes in this locality are said to be marked by much less rapidity and virulence than are characteristic of other forms, and with such harmlessness to the deeper articular structures, that rupture of the distended synovial sac, and infiltration of the soft parts of the thigh, may take place even before the subjacent bony structure has become impaired.

So far as our experience goes, a primary inflammation of the synovia is almost invariably of an acute nature in children, and is thus of much importance

as a diagnostic sign, while true articular osteitis is *always* chronic, both in its character and manifestations.

The existence of subluxation, considered apart from the other conditions associated with it, is not a characteristic sign of the disease; for any degenerative process about the joint which involves its ligaments and cartilages would tend to produce the same result; but, when considered with the other diagnostic signs of osteitis, it assumes a greater importance.

It is not uncommon for malposition of the articular surfaces of the tibia and fibula, with rotation on their axes, to occur as a sequel of acute or chronic inflammation of the joint. When, however, the cause has manifested itself as a degeneration which for many months previously has had its seat apparently at or above the condyles of the femur, but which subsequently has involved the joint, we must usually attribute the displacement to the results of a disease external to the synovial membrane, which has extended thither by contiguity of structure, and overcome the resistance offered chiefly by the anterior crucial ligament. Rarely is it attributable to a cause differing somewhat from the latter—namely, the extension of a chronic inflammatory process located in the periosteum about the condyles, which, judging from the early enlargement of the latter existing in osteitis, must have been associated with proliferation of bone-cells. It is said, however, that a true periostitis is not generally characterized by an exaggerated tendency to new osseous formation, which is one of the characteristics of the form under consideration, but rather to disintegration of the affected tissues; or, by cutting off the nutritive supply to the subjacent bone, to caries or its allied degenerations, to which, with more reason, might be attributed the hypertrophy which so often exists. In cases where the inflammatory process confines itself to the articular extremity of the femur, the latter is much increased in size, while the only evidence of synovial inflammation which commonly exists, is pain and stiffness about the joint, which might, with equal probability, be due to inflammatory thickening, shortening, and infiltration of the periarticular tissues; occasionally, the presence of fluid within the capsule is apparent as a secondary symptom, though little inconvenience arises from it—in fact, the functions of the limb seem often less impaired than when none exists.

In very many cases, if not all in which the existence of osteitis was evident, there was enlargement of the internal condyle, for this one is more generally affected than its fellow, as shown by recorded measurements.

It has been denied by some authorities that true intrinsic enlargement of these occurs, but that the apparent increase in bone substance is caused by the deposition of osseous material upon the surfaces of the condyles. Paget states that by far the most common seat of the new formation is either in the periosteum, or between it and the bone, which view is shared by Billroth as well. One of the first to attach to this a different meaning was Roser,* who considered cell-proliferation in the epiphyseal cartilage a frequent cause of the elongation. The existence, however, of pathological specimens showing undoubted intrinsic enlargement of these parts, together with clinical experience afforded by measurements of joints not infiltrated, tend to render this rule not only fallible, but attended with many exceptions. For, numerous post-mortem examinations of the knee-joint, with a view of ascertaining the normal size of the condyles, as well as of the parts overlying, have enabled those who will, to estimate with some degree of accuracy the amount of enlargement which exists.

Although those cases of condylar enlargement, accompanied by bone-proliferation, exceed by far those in which suppuration predominates, it is not rare to find, on sawing the outer layers of the epiphysis of bones thus enlarged, a central degeneration, which is shown either by the existence of cheesy material, which has become more or less completely encapsulated, or pus, the final manifestation of a long series of degenerative processes. In cases of this nature, however, the previous history of the patient will usually be found to exhibit some of the more positive signs of osteitis. We have in our possession notes of cases in which infiltration in the vicinity of the joint had existed for many months, sometimes improving, but as often relapsing to its former condition; the other signs of osteitis being likewise present. Examination of the parts after death, however, showed that although the bony structures of the joint were markedly increased in size, there was no evidence of caries on their surfaces; but upon dividing the condyles into lateral halves, a considerable quantity of thick pus flowed from their centres, disclosing large cavities there, which sometimes occupied fully two-thirds of their substance.

The importance of the faradic current as a diagnostic measure has been highly estimated by some who have had much experience in this department of surgery. It is claimed by them that the muscular tissues about an osteitic joint are markedly less sensitive to this current, even in the earlier stages of the affection, and that the phenomenon is usually not present to any extent in synovitis, rendering this, therefore, an important subject of consideration in the differential diagnosis. For some time we have improved the opportunity to examine electrically many cases coming under our observation, using both the primary and secondary currents with slow and rapid interruptions, and testing cases illustrating various forms of knee-joint disease. The result of these examinations has been to impair our confidence in its claims; for in those presenting all the other signs of osteitic disease, which was often far advanced, the contractility was diminished about in proportion to the muscular atrophy, the responses being equally good in those cases presenting the same condition of the muscles from other causes.

During the first stage of the affection it was diminished, on an average, about one-third, though sometimes much more; for it is quite natural that diminution of electric contractility should exist in all cases where any infiltration is present—the fact that this condition interferes with the free transmission of the current being unquestionable. In cases of synovitis, arthritis, and periarthritis, this symptom existed in about the same degree.

Verneuil has lately stated that true anchylosis from arthritis of a joint is of very rare occurrence, but that it is simulated by the contraction of the muscles and periarthritic tissues in their attempt to immobilize the joint for the relief of pain. While considering this view, none too radical as regards the disease spoken of, we imagine even less few exceptions to this rule occur as the result of true osteitis; for, so far as observation of a considerable number of such affections will enable one to judge, fixation of the limb by fibrous adhesions, muscular con-

* Handbuch der anatomischen Chirurgie, 1875.

tracture, and changes in the tissues overlying the joint, is a most common sequel of the disease, while fusion of the articular surfaces of the bones is of quite rare occurrence. In the cases just referred to, an articular disease, either far advanced toward recovery, or presenting all the signs of a progressing inflammation, was too apparent by its attendant symptoms to admit of doubt. The joints were firmly and almost immovably fixed at a more or less obtuse angle, and in some instances not the slightest motion between the articular surface could be elicited. But these cases, apparently hopeless so far as the obtainment of a useful limb was concerned, have, with a few exceptions, become gradually so much more extended under the influence of continuous extension by a brace used for the purpose, that the act of locomotion was performed with comparative ease.

A PRELIMINARY REPORT UPON THE USE OF DILUTE NITROUS OXIDE GAS IN THE TREATMENT OF MELANCHOLIA AND NERVOUS EXHAUSTION.

By JOHN ELLIS BLAKE, M.D.,
AND
ALLAN McLANE HAMILTON, M.D.

Several years ago the attention of one of us (Dr. Blake) was called to the use of nitrous oxide, or laughing gas, as a remedy in certain asthenic nervous disorders by Mr. Johnston, the manufacturer of dental instruments in this city, who had been informed by one of his correspondents in regard to the wonderful efficacy of an admixture of nitrous oxide gas and air in insomnia, "nervous debility," and headache. Dr. Blake immediately began a series of experiments, which we have jointly continued, and we understand that Dr. Alexander Skene, of Brooklyn, to whom Dr. Blake some time ago communicated his investigation, has had results scarcely less favorable than our own.

The administration of the gas is for its stimulating effects, and taken with a greater or less proportion of air, it produces a species of exhilaration with very little subsequent reaction, the primary excitement being akin to that which commonly follows the use of champagne or any sparkling dry wine. There is a feeling of lightness and buoyancy, the individual becomes loquacious, while the heart's action is increased, and there is a momentary dizziness. The administration of the gas should not produce other effects, for intoxication and anæsthesia imply a step beyond stimulation, and therefore should be avoided. If the fingers grow numb, or if any object upon which the patient fixes his gaze becomes blurred, then should the use of the gas be discontinued.

From the condition of exhilaration described the patient recovers, and for the rest of the day feels decidedly brighter and more active. If he be depressed before the gas is given, or suffers from an attack of "the blues," the effect is much more marked. Patients who have placed themselves under our care, who have at first been dejected, who have worried about their absence from home, or about their children, or business, have in a few days become entirely accustomed to their new surroundings, and have indulged in amusements and pursuits they never were able to enjoy. It virtually takes the place of alcoholic stimulation, without depression, and for this reason we suggest its use in the treatment of alcoholism, especially in the early stages of delirium tremens. As a remedy in insomnia it has no equal, and when *not* given just before bedtime, but in the morning or middle of the day, it, as a rule, procures refreshing sleep, even for those who have relied entirely upon anodynes.

In cases of so-called "spinal irritation," or in cases of "nervous prostration," in women who have no discoverable uterine disease, we have good reason to think it acts admirably, as it also does in hysteria, or the form of nervous derangement bordering on melancholia. When the circulation is defective, and when there is lividity of the hands, constipation, slow pulse, and rough, scurvy, mud-colored skin, it in a short time greatly betters the condition of the patient. It, so far as we have seen, favors the assimilation of food, hastens the action of iron, and increases functional activity. Appetite and sleep, and disposition to take exercise, are all improved.

The remedy has been used much in its compressed or liquid form by quacks, under the names "compound oxygen" or "liquid oxygen," and even in such hands has cured many persons who have gone the rounds of the legitimate profession.

It is not indicated in sthenic affections, or when there is a tendency to cerebral congestion or excitement, but rather for the irritability of exhaustion. It therefore, we have found, increases the trouble in vigorous, full-blooded subjects. The gas should be used well diluted with air, which may be accomplished by opening the valve near the mouth in the instrument provided for the purpose. Daily inhalations of not less than twenty gallons of gas should be used, the amount of air taken as well into the lungs being sufficient to prevent intoxication.

We are now engaged in experiments with nitrous oxide in the treatment of the chronic insane, and will publish our observations at another time. At present we deem it our duty to suggest to the profession the employment of a remedy heretofore used only for surgical purposes, which, in its new method of employment, promises a great deal.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

DOUBLE AORTIC MURMUR—DILATATION EXCEEDING HYPERTROPHY—OBSTRUCTION TO RETURN CIRCULATION—IMPORTANCE OF RECOGNIZING DILATATION OF THE RIGHT AURICLE.

The following case was interesting on account of symptoms referable to the heart. A male patient, æt. 50 years, a plasterer by occupation, had been sick thirteen months with what he called rheumatism in the shoulders, in the muscles, and backache, but had not at any time had swelling of any of the joints. He was first attacked with swelling in the neck, which lasted about six weeks, and since that time had not been able to work. The swelling would come and go, and was not accompanied by any difficulty of swallowing. During the six weeks, at times when the swelling of the neck occurred, he noticed that his face was red and somewhat purple, and since that time he had not been able to work on account

of what to him seemed to be a "rush of blood to the head." He was not able to lie upon the left side, felt weak, and suffered from shortness of breath on going upstairs, and when he bent forward he was "kind o' dizzy." He had had a cough without expectoration other than mucus, ever since he had been sick. Twenty-five years ago he had a small single sore upon his penis, but had never had sore-throat, eruption, or falling of the hair. He had slight lumps in the groin soon after the development of the sore on the penis, but, together with the sore, they disappeared without special treatment.

Physical examination.—On inspecting the surface of the trunk, an enlarged vein was noticed in the central portion of the upper part of the abdomen, and a visible movement over the epigastrium, and extending to the left of the nipple considerably. The maximum point of heart-beat was to the left of the nipple and downward; it was more forcible, and was felt over a larger area than normal, and its rhythm was lost. The scapulæ moved freely on full inspiration. Vocal fremitus was increased on the left side as compared with the right. On *percussion*, dulness, not flatness, was found upon the left side. The questions to be answered were these: Was the swelling and blueness of the face upon exercise, or when he held his head forward, or when he was in the horizontal position, due to some obstruction to the return circulation existing outside of the heart, or was the cause within the heart?

Was the displacement of the apex of the heart to the left the result of hypertrophy, with or without dilatation?

What gave rise to the increased vocal fremitus with dulness over the right chest posteriorly?

There was a pleuritic friction-sound over the left chest. There was no evidence of pulmonary consolidation. There was no increased area of dulness on a level with the third rib toward the left; but the area of dulness extended to the right beyond the normal limits to a small extent. There was no impulse over this region. There was an aortic regurgitant and aortic obstructive murmur, mediastinal tumor was excluded, aneurismal or otherwise.

External obstructions to the return circulation were excluded. There must be some obstruction to the return circulation in the right auricle, such as comes from insufficiency of tricuspid orifice, or in connection with disease affecting the left side of the heart, in order to develop blueness of the face when the patient lies down. In this case, that condition was believed to be due to the fact that the eccentric hypertrophy was not sufficient to overcome the dilatation. It was not simply a case of aortic regurgitation and obstruction, with hypertrophy, but it was regarded as a case of aortic valvular lesion, with hypertrophy insufficient to compensate for the dilatation, and therefore it was impossible for the heart to empty itself completely at any time. As a result of that, failure in the right heart follows, and there is disturbance of the return circulation. That was the reason given why one man with double aortic murmur gets along very well—namely, the hypertrophy compensated for the dilatation—while another patient gets along badly because the hypertrophy is not sufficient to overcome the dilatation.

The patient did not suffer from vertigo when walking or sitting. He had had pleurisy at some time upon the left side posteriorly. It was remarked that dilatation of the right auricle, so that it does not have its normal power to empty itself, is a very common cause of the turgid condition of the vessels of the head and upper extremities, and one not sufficiently appreciated in physical diagnosis relating to diseases of the heart and the aorta. What can be accomplished by treatment? was the next question. Rest was set down as all-important. We should never exercise sufficient to tax the heart in the least. At the same time, the nutrition of the cardiac muscle should be increased, if possible, and that can be best done by taking a concentrated nitrogenous diet, small doses of iron, and with those measures $\frac{1}{100}$ of a grain of digitaline t. i. d., simply to stimulate the muscle of the heart sufficient to increase its nutrition. With proper management, it was thought that life might be prolonged from four to six years.

VARICOSE ULCERS—RUBBER BANDAGE.

Some cases of varicose ulcers on the lower extremities were seen, which were being treated by the application of the rubber bandage. A general experience is that as soon as the bandage is applied the pain is very much modified, or entirely subsides, and improvement is marked and rapid. The ulcers commonly heal within ten or twelve days. In one case the rubber bandage was used upon the right leg, and an ordinary rubber-bandage was used upon the left leg, and the progress had been nearly equal.

SUBACUTE SYNOVITIS OF THE KNEE-JOINT.

A patient afflicted with the disease had worn the rubber bandage with marked benefit. The pain was relieved promptly, and the swelling diminished rapidly. It is regarded as better than pressure obtained by the use of compressed sponge. The bandage should be removed as often as it becomes loose, and then reapplied. In the case before us the swelling had almost entirely subsided, there being little more then that slight thickening of the tissues which almost invariably remains.

FRACTURE OF THE LOWER JAW WITHOUT DISPLACEMENT.

A male patient was admitted to the hospital, suffering from an abscess of the left side of the face. A few days before admission he fell and struck upon the side of his face, which afterward began to swell and pain him severely, and it was only with great difficulty that he could open his mouth at all. There was one feature of the case which gave rise to the suspicion that he was suffering from something besides abscess of the face, and that was a peculiar fetor of the breath—always present with fracture of the jaw. On account of the great swelling, the surgeon was not able to examine the jaw sufficient to enable him to make a positive diagnosis. An opening in the side of the face was subsequently made and a large quantity of pus was evacuated, and then, the tumefaction was so reduced that examination was possible, and distinct crepitus was obtained. The fracture was near the angle, and the peculiar feature of it was that there was no displacement. The swelling about the seat of the fracture tended to keep the bones in position. It had had no dressing except a roller-bandage.

COMPOUND FRACTURE OF THE LEG—DIFFICULTIES OF REDUCTION.

The fracture was caused by a bar of iron falling upon the middle part of the left leg of a man in good health and of middle age. The lower end of the upper fragment of the tibia projected through the integument. To reduce the fracture, so that the end

of the bone would be entirely within, extension and counter-extension were employed, but all efforts in that direction failed. Extension and counter extension, accompanied by an incision in the soft parts, and pressure upon the projecting fragment so as to depress it and bring the bone into proper position, were then resorted to, and failed. Excision of portion of the projecting fragment was then resorted to, and complete reduction accomplished. The clotted blood was carefully wiped away, and the limb was dressed in a fracture box. The surgeon remarked that there is an objection to removing a large fragment of bone, for the reason that it might delay union or be the cause of non-union. [Gangrene appeared, and the limb was subsequently amputated.]

Progress of Medical Science.

On the Use of Carlsbad Water in Diabetes Mellitus. Dr. Mayer, of Carlsbad, concludes a paper on this subject with the following résumé:

I. Diabetes mellitus is an incurable disease.

II. The Carlsbad cure, in a large number of the cases, relieves the most troublesome symptoms, improves the general condition of the patients, and prolongs life.

III. In cases which have reached a certain advanced stage, or which are complicated with other severe diseases, Carlsbad water proves useless.

The use of Carlsbad water is indicated: 1. In all cases of diabetes mellitus of the first degree, whether of the gastro-enterogenic (chylogenic), hepatogenic, or neurogenic variety. The tolerance for the hydro-carbons will increase in proportion to the fidelity with which the patient adheres to a strict nitrogenized diet, not only while under treatment, but at all other times. 2. In those cases of the second degree (severe form), in which the greater part of the albuminates ingested are utilized in the body, and in which the organism does not have to make good from its own organic constituents any deficiency in the supply of nourishment, or at least when the deficiency to be supplied is only very inconsiderable; in other words, whenever under an exclusively meat diet the weight of the body diminishes only very little or not at all. 3. In cases falling under 1 and 2, but complicated with furunculosis or carbuncles. 4. In cases falling under 1 and 2, complicated with nervous amblyopia or cataract, provided the general condition is free from manifestations of marasmus. 5. In cases falling under 1 and 2, complicated with slight pulmonary affections, such as catarrh or circumscribed chronic pneumonia. 6. In obese patients subject to more or less frequent attacks of angina pectoris, that can be ascribed to the cardiac weakness consequent on fatty heart. 7. In cases falling under 1 and 2, complicated with albuminuria, whether the latter appeared at the outset of the diabetes, or only after the disease had already existed for years.

The Carlsbad water is counterindicated: 1. In those cases of the second degree (severe form) in which only a small part of the albuminates ingested are utilized, and the organism must make good from its own organic constituents this great deficiency, in which, in spite of a large excretion of sugar (100 to 200 grms. pro die), enormous quantities of urea are discharged with the urine. Fürbringer briefly characterized this condition of affairs as one "in which the relative percentage of sugar is very small." Cases of this sort must progressively emaciate and proceed rapidly and without intermission toward a lethal termination. 2. In cases of diabetes mellitus in which cardiac weakness leads to gangrene of the skin. 3. In cases complicated by affections of the eyes that are directly dependent on severe cerebral disease—*e. g.*, atrophy of the optic nerves, hemiopia due to cerebral tumors, etc. 4. In cases complicated with phthisis, tuberculosis, or gangrene of the lungs. 5. In cases in which asthmatic difficulties persist, or the attacks of angina pectoris remain frequent, although the formerly obese patients have emaciated considerably. 6. In cases in which the albuminuria is accompanied by marked anæmia or hydræmia, or where it is symptomatic of nephritis or of amyloid degeneration of the kidneys. 7. In cases of the second degree (severe form) complicated with constitutional syphilis. *Memorabilien*, Nov., 1878.

Physiological Effects of the Formiate of Soda.—Mr. Arloing reports the results of a series of experiments with this drug. When successive doses of a 20 per cent. solution are injected slowly into the veins of a dog or horse, the following phenomena on the part of the circulatory system are observed: after the first injections the heart beats more slowly, the capillaries of both the general and the pulmonary systems dilate, the arterial tension diminishes, and the diastolic or constant rapidity of the blood-current increases in the centrifugal vessels; when the quantity introduced into the blood has become large, the heart's action becomes more rapid and the systole weaker. If a very large dose of the formiate be injected directly into the right ventricle, it causes retardation or even arrest of the heart's action. This arrest may be permanent; if not, the heart begins to beat again after a longer or shorter interval, according to the quantity of the formiate injected. After the action of the heart has been re-established, the symptoms are the same as after the injection of large doses.

Small doses increase the number and depth of the respiratory movements. Moderate doses prolong expiration, and are sometimes followed by a series of short, rapid respiratory movements, separated from one another by a deep inspiration and a prolonged expiration. Large doses accelerate the respiratory movements and diminish their depth. A very large dose causes, immediately after the injection, a short arrest in expiration; the respiration is soon re-established, and is for a time exceedingly rapid, gradually increasing in depth. After twenty or thirty seconds these phenomena are replaced by a diminution in the rapidity and depth of the movements of the thorax, and by a tendency to a pause during expiration.

The formiate of soda is toxic when the dose exceeds 1 grm. for each kilogramme (15 grs. to 2¼ lbs.) of its live weight of the animal. Death is ushered in by short inspirations separated by expiratory pauses, which rapidly grow shorter and shorter. The movements of the chest are arrested in expiration. The heart continues to beat for about fifty seconds after respiration has ceased, its pulsations gradually becoming slower and weaker.

The formiate of soda lowers the animal temperature. In gradual poisoning, the temperature may fall 4.5° F. in an hour. This fall of temperature is due partly to the marked dilatation of the superficial capillaries, partly to the diminution in the depth of the respirations, and more especially to the modifica-

tion of the pulmonary exchanges and the retardation of the organic combustion. When the expired air was analyzed during the action of the drug, it was found to contain less carbonic acid and more oxygen than under normal conditions, showing that the diminished elimination of carbonic acid by the lungs was accompanied by a diminished absorption of oxygen. When the gases of the arterial blood were analyzed, both the carbonic acid and the oxygen were found to be diminished; hence, the diminished absorption of oxygen by the lungs was accompanied by a diminished production of carbonic acid in the tissues. The effects of the drug on the elimination of urea were not studied.

It follows from the above that the formiate of soda must be classed among the defervescent remedies. It may, perhaps, prove useful in cases where the action of the salicylate of soda is distrusted, as it does not cause congestion of the kidneys, and does not affect the heart as violently as the salicylate.—*Arch. gén. de méd.*, November, 1879.

Fatal Hemorrhage after Vaccination.—Heyfelder and Kersten have each reported a case of profuse, but not fatal hemorrhage after vaccination, and Henschel and Stromeyer have reported cases of fatal hemorrhage after the same operation. In all these cases the patients belonged to families that were known to suffer from hæmophilia. To these cases—which are all of which he could find records in German medical literature—Dr. Pott, of Halle, adds another, which is peculiar from the fact that the hemorrhage probably depended on leukæmia. The patient, a well-nourished girl, aged seventeen weeks, was vaccinated by four shallow incisions on each arm. The incisions bled very freely at first, and the bleeding is said to have continued for two days. The pock did not take regularly, but on the third day vesicles containing a bloody serum formed over the incisions. On the fifth day some of these vesicles burst, and for two days a large quantity of a lymph-like fluid exuded from them. The hemorrhage then returned, and on the ninth day, when Dr. Pott saw the child, a thin, bloody, serous fluid, which had but slight tendency to coagulate, was oozing from the incisions. The child was well nourished, but was very anæmic, and its skin had a wax-like color. The extremities and face were cool, and the child shivered as if with cold. The respiratory and circulatory organs presented nothing abnormal, but the liver was greatly enlarged; it was firm and smooth, and easily mapped out by palpation. The spleen was also greatly enlarged and firm. The inguinal, cervical, and axillary glands were enlarged. The examination of the blood revealed marked increase of the white corpuscles, the proportion being estimated at one to thirty. The father of the child had frequently suffered from epistaxis, but otherwise there was no discoverable hereditary tendency to hemorrhage. In spite of all efforts to stop it, the hemorrhage from the incisions persisted, and cutaneous extravasations formed on different parts of the body. The child grew rapidly weaker and paler, and died in convulsions on the fifteenth day after vaccination. An autopsy was refused, but the diagnosis of leukæmia was undoubtedly justified by the symptoms. The pock used had been taken directly from a cow, and had been used at the same time on thirteen other children with perfect success. Within the last few years it has been discovered that leukæmia is a relatively frequent disease of childhood, and the connection between that disease and the hemorrhages of very anæmic children has also been pointed out.—*Berl. klinische Wochenschrift*, Nov. 3, 1879.

Case of Ileus treated successfully with Mercurius Vivus.—Dr. Rintelen, of Hagen, Westphalia, reports this case: The patient, a woman, forty-five years of age, had suffered for ten days from obstruction of the bowels, with intense pain and feculent vomiting, and had fallen into a state of marked collapse. During the first few days of her sickness large injections of water into the colon had several times produced free evacuations, followed by temporary relief, but during the last five days no fæces had been passed at all, and her condition had rapidly grown worse. Injections of air and all other methods of treatment had proved futile. As the case was desperate, the diagnosis of ileus could be made almost with positiveness; and as the operation of laparotomy would not be permitted, Dr. Rintelen decided, as a last resource, to try the effects of metallic quicksilver. The condition of the patient, in spite of the collapse, was favorable for a trial of this remedy, as the peristaltic movements were still very strong, and there had been no general peritonitis to glue together or soften the intestines. Accordingly, 300 grms. (nearly ten ounces) of quicksilver were administered in three doses, at intervals of an hour. The vomiting ceased after the first dose, but the nausea persisted, and the condition remained otherwise unchanged until the following morning, when the first evacuation from the bowels took place, fifteen hours after the first dose of mercury had been taken. During that day the patient had nine thin passages, and at the same time the peristaltic movements became less violent, the pain diminished greatly, and her general condition improved. From that time on she steadily improved, but the bowels were loose for several weeks, and she suffered considerably from pain for a few days. No traces of the mercury were found in the stools until the third day, seventy-two hours after its administration. On that and the three following days a few globules were found in most of the stools, but on the seventh day she passed at one time over five ounces of mercury, on the eighth day about an ounce and a half, and on the ninth day nearly two ounces, and for some days longer the stools sometimes contained small quantities of it. On the twenty-third day the patient was discharged cured. No symptoms of mercurial poisoning were observed in this case.—*Berl. klin. Wochen.*, Nov. 3, 1879.

Gastrotomy in a Case of Œsophageal Stricture.—Dr. S. Herff, of San Antonio, Texas, reports to the *St. Louis Courier of Medicine* a case in which the above operation was performed. The patient, a child of seven, had swallowed caustic lye a year before. Since then she had not been able to swallow solids, nor even liquids, all of the time. As the child was failing steadily, and bougies did no good, an operation was determined on. Dr. Howse's plan was followed: an adhesion was first excited between the stomach and abdominal wall by a double row of sutures. Then an opening was made into the stomach. The operation was performed successfully, without fever, peritonitis, or any bad symptom. The child is now fed entirely through the fistula: finely chopped beef, or other meat, generally raw, is pushed through the opening. Liquids are poured in through a funnel. Saliva enters the stomach somewhat by the act of swallowing; she spits on some of the food. Since the operation she has continued well and increased in weight.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 31, 1880.

CONCERNING ETHERIZATION.

PATIENTS are so frequently brought under the influence of an anæsthetic, and so many internes of hospitals claim to be adepts in the administration of the drug, that it may appear almost like presumption on our part to claim that there is anything yet to be learned on the subject. It is true that we now and then hear of a death from chloroform, but this circumstance is generally explained by the fact that chloroform is dangerous. The usual verdict of the coroner's jury, that no one is to blame for the result, helps the professional man to the conclusion that the prevention of sudden death is impossible, and that sulphuric ether should always be used when an anæsthetic is required. Chloroform has such a reputation for treacherous behavior, that those who dispense its vapor are generally very cautious how they proceed, and narrowly watch the pulse and the respiration during the whole time the patient is insensible. It is fair to assume that by this care many fatal results are prevented. What, however, induces caution in the administration of chloroform has usually the contrary effect when ether is used. In other words, because ether is known to be an eminently safe anæsthetic, the method of its administration and the degree of insensibility produced appear to be matters of purely secondary consideration. That hundreds of deaths have not been due directly to the clumsy—nay, ignorant administration of ether, is a wonder to any one who has witnessed many surgical operations, especially in our large hospitals.

Having assumed thus much, we come to the point of our remarks by insisting that greater care should be exercised even in the administration of sulphuric ether. Aside from the fact that death may occur from etherization, patients are very apt to suffer, if not bodily, at least mentally, from the oftentimes rough, if not positively cruel handling, which by many is thought to be necessary to overcome resistance.

By many patients the horror of being held down and almost choked with ether is greater than that of the operation itself. This process of overwhelming with the anæsthetic may not be considered dangerous by the giver, but it is dreadful to the subject. A very common practice is to crowd the sponge over the nose and mouth of the patient, and give him as little air as possible. Anæsthesia is then induced with great rapidity. Time is not only saved, but considerably less ether is used. These circumstances hardly weigh against the suffering of the patient, who is held down by main force—straddled and sat upon, if necessary—to control what is with a grim humor called his period of excitement. In one of the hospitals of this city there is a very suggestive caricature of a patient being anæsthetized in accordance with the generally accepted method. The gentleman giving the ether is at the head of the operating-table, holding the sponge tightly over the patient's face, and steadying the head by grasping it between his arms. The patient is represented in the act of struggling; the chest is arched upward, the head is thrown backward, the extremities are distorted, and no less than six assistants are exerting their utmost strength to compress the patient within proper limits. There is such a mixture of limbs, so much confusion of angular articulations, of hands, of heads, and of feet, that it is at first somewhat difficult to make out where the patient begins and where the assistants leave off. To one who never heard of anæsthesia it would naturally appear that a half-dozen Othellos were repeating the celebrated smothering scene, with variations. And yet this is a picture which is a truthful representation of what very frequently occurs as a preliminary to a surgical operation.

When we are ready to acknowledge that this crowding process is unnecessary, we are prepared to ask if it is not a trifle cruel.

Every surgeon of experience has proved the utility of gradual etherization to begin with. Long, deep inspirations of the vapor mixed with atmospheric air—the sponge held a little distance from the face—have been followed rapidly by complete insensibility. When this stage is reached the cone containing ether can be placed over the mouth and nose of the patient. He then breathes only such air as is admitted through the apex of the cone and is necessarily saturated with ether. Under such circumstances profound anæsthesia can very frequently be induced with scarcely a struggle on the part of the patient. At least, if it is necessary to restrain his movements, he is wholly unconscious of it, and does not suffer bodily or mentally.

Another advantage of the gradual method of initiating etherization is the comparative tranquillity of

mind of the patient, a condition which of itself invites speedy insensibility with a corresponding small amount of subsequent excitement. On the contrary, nothing would naturally tend to excite a patient more than the idea that he was in danger of being suffocated. And nothing more forcibly conveys such an impression than the direct application of a sponge to the mouth and nose while the patient is conscious. But the danger of actual suffocation is far from being imaginary. Very often the operator is forced to remove the sponge, even during the first stage of anæsthesia, because there is an ominous hitch in the breathing. That the patient is oftentimes quickly rallied is to the credit of the ether rather than to the method of giving it. Again, this danger is not confined to the first or even the second stage, but is often witnessed when the patient is ready for the knife. It is perhaps unnecessary to remind most of those gentlemen who attend operations, how often artificial respiration is resorted to because the breathing is interrupted, the lips blue, the eyes staring, and the pupils dilated. When the cause for this is accurately estimated, it is generally found, except in operations around the mouth with its attending inspiration of blood, that the gentleman giving the ether does not appreciate his responsibility. In nine cases out of ten he is watching the operation and neglecting the anæsthetic. Generally some one of the spectators becomes nervous over the condition of the patient, and is able to give a warning in time. But some time the warning will come too late. We have seen so many patients who have been almost given up for dead while under the anæsthetic, that we have thought there was but a little farther for them to go. And this is the reason for saying a few words in season.

THE SANITARY CONVENTION AT DETROIT.

The Sanitary Convention undertaken under the auspices of the Michigan State Board of Health, met at Detroit, January 7th and 8th, and was a very successful affair. Many of the particulars in regard to it have been given in a previous issue. The prominent topics discussed were School Hygiene, Ventilation, Milk; Cooking-Schools, Adulterations, Abattoirs, Water-Supply, and Cosmetics.

The subjects were generally treated in a popular and practical manner, few being of a purely medical or scientific nature. Yellow fever received a dramatic portrayal from Dr. R. C. Kedzie, and the popular topic of neurasthenia was discussed by Dr. W. H. Rouse. Some most valuable suggestions were given by Mrs. Wm. Jennison on the subject of cooking-schools. The great usefulness of these institutions was shown, as well as their popularity wherever they had been properly introduced. They have become important educational factors in England, Scotland, France, Holland, Prussia, and Switzerland. Self-supporting schools also exist in this country in New York, Boston, Washington, Illinois, North Carolina, Indiana, and Kansas. The Bureau of Education has devoted a circular to the distribution of information concerning them. The medical press have of late been recommending that the doctor pay some attention to the kitchen. It becomes him, therefore, to keep his eye on the cooking-schools and the educational opportunities of the *cordon bleu*.

Two papers were read on subjects pertaining to school-hygiene. These were timely, and presented very forcibly the physical dangers that environ the growing child. There are few subjects in hygiene that better deserve study and active discussion.

The work of the Sanitary Convention, on the whole, was excellent, covering as it did a wide range of practical topics. It compares very favorably with that of the American Public Health Association, at Nashville.

A NEW RHINOPLASTIC OPERATION.

The operation for the replacement of a lost nose is one which, apart from its surgical importance, has always taken a deep hold on the public interest and imagination. A finely developed nose is the finishing touch with which evolutionary force crowns our physical structure. Its loss is an æsthetic as well as an olfactory one, and its restoration is a contribution of science to plastic art which for once brings out the two in a conspicuous harmony. Rhinoplasty is among the few operations in surgery to which a statue has been erected by public citizens.

The existence of this popular interest in rhinoplasty has recently been shown by a long article in a leading daily journal, describing an operation of this kind at Bellevue Hospital. The patient, a healthy young man, had lost his nose from a lupoid affection two or three years ago. The disease, having destroyed the nose, ceased to progress. The contraction of the cicatrices, however, produced ectropion in both lids. After waiting for over a year, as the disease did not show itself again, plastic operations for the relief of the ectropion were successfully performed by Dr. Sabine. These operations were followed, a short time ago, by one for the restoration of the nose, the middle finger of the left hand being used to supply the needed tissue. The nail of this finger was first removed, and its matrix cauterized. Then, at a subsequent period, the patient being etherized, an incision was made along the palmar surface of the finger, and the skin dissected back on either side. These flaps were united by fine sutures to the sides of the nasal openings. During the operation the patient was nearly strangled by the blood which poured through the nares into his larynx. Laryngotomy was instantly performed, and relief thus given. The operation was then finished, and the hand firmly bound to the face by plaster-of-Paris

bandages. The patient has, we believe, since been doing well. As union takes place, the digital arteries will be tied, and eventually the finger amputated. Such further operations as are necessary for securing greater symmetry and beauty to the new organ will be performed.

It should be noted that a full description of this operation appeared in the *Herald* and the *Times*, and yet no surgeon's name was introduced. This is an evidence of good taste on the part of all concerned that is very commendable.

DISCUSSION OF LUNACY REFORM.

We publish elsewhere a letter from Dr. L. C. Gray, presenting the subject of lunacy reform, and asking that our columns be thrown open to a full discussion of both sides of the question.

We have no prejudice in this matter, and have always been ready to publish any proper communication concerning it. We have long been sincerely convinced that the care and treatment of our insane were very imperfect. It seemed due to the profession that the matter be agitated, and improvement secured, if possible. This position we took long before the birth of the Neurological Society's petition and of the Albany Committee. That our views agree with those of that Society in the points indicated by our correspondent, is a pleasing coincidence which we are happy to admit. That they coincide, however, with the method and matter of its ill-fated petition, with its unhappy mode of getting signers for the same, with the newspaper notoriety of some of its charges, or with the wisdom of its management at Albany, we cannot so fully agree.

We have, however, every confidence in the essential sincerity and earnestness of the Society's efforts for lunacy reform. Evils exist. Reform is necessary to our reputation as an enlightened and humane State. These facts are to be impressed upon the public until a sentiment is aroused which will demand a change. The Neurological Society has certainly done good work in arousing this public sentiment, and in collecting and presenting facts to justify it. We hope it may do work in future which will abate some of the distrust which a few of its acts in the past have, perhaps unjustly, aroused.

Meanwhile, we can give a moderate space to communications, *pro* and *con*, on the subject of lunacy reforms.

ATTEMPT TO PROHIBIT VIVISECTION.

On January 21st, Mr. Bergh had a bill introduced into the State Legislature to abolish vivisection. It reads as follows:

"SECTION 1.—Every person who shall perform, or cause to be performed, or assist in performing, in or upon any living animal an act of vivisection, shall be guilty of a misdemeanor.

"SEC. 2.—The term 'vivisection' used in this act shall include every investigation, experiment, or demonstration producing, or of a nature to produce, pain or disease in any living animal, including the cutting, wounding, or poisoning thereof, except when the same is for the purpose of curing or alleviating some physical suffering or disease in such living animal, or in order to deprive it of life when incurable.

"SEC. 3.—This act shall take effect immediately."

With the bill is a memorial, reciting the cruelties inflicted upon the brute creation by learned and scientific, but misguided medical men. It further states, what is atrociously untrue, that vivisection has been universally condemned by the more eminent members of the medical profession in Europe. It states that a bill was introduced into the English Parliament at its last session, but does not touch upon the fact of its failure to pass.

Both bill and memorial are too radical, unfair, and unreasonable to deserve of themselves serious attention. The cause of anti-vivisection has, however, reached a factitious importance from its constant agitation by bumptious and ill-balanced philanthropists. The medical profession ought, therefore, to keep an eye upon the present bill. Its passage would be a serious calamity.

NEW MEDICAL JOURNALS.

THE present month of January brings to our table eight new periodicals devoted to the educational advancement and literary needs of the medical profession. The appearance of such new journals is liable to suggest parturient analogies, and yet they are hardly apt. A new journal is not born in the manner of mortals, though it often meets their fate. It must spring forth at once in full maturity. It must show an immediate and well-trained activity; it needs at once the richest diet and the best typography; it requires its greatest wisdom at the outset. In such manner Minerva sprang full-armed from the head of Jove; but no recent obstetrical phenomena bear any resemblance to the appearance of a new periodical.

Among the octet to which we have referred, we notice first that Dr. Walsh, of Washington, announces a *Retrospect*, a quarterly compendium of American medicine and surgery. It is unique in that it confines itself to American work alone. The contents of the first number have a value which certainly proves that one need not go out of this country to compile a most excellent volume. As nearly one-fourth of the selections are taken from the MEDICAL RECORD, we can hardly say less than this.

The Alienist and Neurologist is also a quarterly journal, and is devoted to psychiatry and neurology. It is intended especially to subserve the wants of the general practitioner, and it is edited at St. Louis by

Dr. C. H. Hughes. The first number has interesting articles by Dr. Pliny Earle, on the "Curability of Insanity;" by Dr. G. M. Beard, on the "Sequences of Neurasthenia;" and by Dr. C. H. Hughes, on "Tendon Reflex." Several other original articles, and considerable editorial and selected matter, make the number before us a promising one. Although there is, perhaps, no particular craving, no passionate want, amongst general practitioners for psychiatrical information, we presume that the contributions to this journal find many interested readers.

Dr. S. M. Miller, of Philadelphia, publishes in that city *The Clinical News*, a national weekly journal of clinical medicine, surgery, and gynecology. The typographical appearance, as well as the contents of the first number, are extremely good. Dr. Miller has had an experience in medical journalism which will help greatly towards the success of his new venture. A lecture by Dr. Da Costa, and a communication from Dr. Wm. Goodell on ovariotomy, make up a portion of the original matter.

The January editorial wave, beginning at Chicago in the *Medical Gazette*, circled around to Philadelphia, undulated at Baltimore into the *Practitioner*, passed to Washington, St. Louis, and has even struck the prairies. The *Kansas Medical Index* is a journal which devotes thirty-two pages monthly to medicine, surgery, and the allied sciences. Dr. F. F. Dickman, its editor, writes a sensible salutatory in which he states that the influence of the journal shall be used in the praiseworthy object of getting laws for the protection of the profession in the State against quacks. We only wish that the text of the journal was as pure as the motives of its editor. It would certainly pain and surprise Dr. Morell Mackenzie to learn that he had written "a small monogram on Diptheria," and we hope it is not presuming to suggest that the uniform abandonment throughout the journal of the first "h" in diphtheria is not in accordance with the best orthographical models. Our esteemed contributor, Dr. Hemmingway, will be pleased to know that, under the title of Dr. Hemigrey, in the *Index*, his reputation as inventor of a plaster-of-Paris corset is spreading throughout Kansas.

The *Galveston Medical Journal* discontinued its publication in 1872, owing to three fires, bad health, and unpaid subscriptions. It has now resumed again under the editorship of Dr. Greensville Dowell. The present number is greatly superior in appearance to those of the former series, and, as the only medical journal in a State which has, it is stated, twenty-five thousand physicians, it certainly ought to succeed.

We would say, in conclusion, that we appreciate the hard struggle that must be made by every new journal before it can achieve popularity and success; and we have only kind feelings and good wishes for all efforts to produce honest journalistic work, and to satisfy an honorable ambition.

Reviews and Notices of Books.

THE PATHOLOGY AND TREATMENT OF VENEREAL DISEASES. By FREEMAN J. BUMSTEAD, M.D., LL.D., etc. Fourth edition, revised, enlarged, and in great part rewritten by the author and by Robert W. Taylor, A.M., M.D., Professor of Skin Diseases in University of Vermont, Surgeon to Charity Hospital, New York. One hundred and thirty-eight woodcuts. Philadelphia: H. C. Lea. 1879. 8vo, pp. 835.

IN perusing this volume the reader will be struck with the skill displayed in condensing and arranging the immense amount of material at the disposal of the authors. The great progress which has been made in the study of venereal disease in all its phases, since the appearance of the last edition of this work, necessitated not only thorough revision, but copious additions of entirely new material culled from the numerous original papers which have from time to time appeared during the past few years. There is some alteration in the arrangement of the subjects as compared with former editions, but this is of no consequence.

A new feature of the present edition is the introduction of several diseases resembling syphilis, and liable to be mistaken for it. The additions exceed in bulk one hundred and thirty pages, but are so carefully condensed that they might, under ordinary circumstances, have occupied twice that space. The author in his preface very properly refers to the invaluable aid he received from Dr. R. W. Taylor, whom he very appropriately speaks of as a gentleman "already well known in the United States and abroad by his original communications to our knowledge of venereal diseases, and who was admirably adapted, both by his own experience and by his extensive reading," to engage in such a work. Dr. E. G. Loring, as in former editions, has revised the chapter on diseases of the eye. The present volume, as a whole, has been so altered and improved, contains such an amount of new material, and is so well up to the date of our present knowledge, that it is safe to say that it is without an equal. The work is well printed and is got up in the usual style of the publisher.

THEORY AND PRACTICE OF MEDICINE. By FREDERICK T. ROBERTS, M.D., B.Sc., F.R.C.P., etc. With illustrations. Third American from Fourth London edition. Philadelphia: Lindsay & Blakiston. 1880. 8vo, pp. 1,041.

THE third American edition of this work presents a creditable appearance typographically, and is conveniently compressed into a single volume of decent proportions. The general plan of the work remains unaltered, although throughout there are evidences of careful revision. Particularly is this the case with the chapters relating to the absorbent and nervous systems. Altogether the work fully sustains its former reputation as an useful and thoroughly practical manual for the student and practitioner.

EXAMINATIONS BEFORE THE MEDICAL DEPARTMENT OF THE BRITISH ARMY.—At the recent examination for appointments in the medical department of the British army, seventy-four candidates presented themselves. Of these seventy-two passed, and were sent to Netley as "surgeons on probation."

Reports of Societies.

NEW YORK THERAPEUTICAL SOCIETY.

Stated Meeting, Dec. 19, 1879

DR. A. JACOBI, PRESIDENT, IN THE CHAIR.

PRELIMINARY REPORT ON THE TREATMENT OF CARIES OF THE ANKLE-JOINT BY THE EXPECTANT METHOD AND OTHERWISE.

DR. T. E. SATTERTHWAITE, chairman of the committee on "Surgical Procedures and Appliances," presented a preliminary report on the above subject, which consisted in a brief outline of the history and a summary of twenty-four cases of caries of the ankle-joint studied with reference to method of treatment, duration of suppuration, and final condition of the joint at a recent examination. The duty assigned the committee was to obtain data relating to the comparative methods of treating caries of the ankle-joint, whether by excision, gouging [chiselling and spooning], extension, rest, or the expectant plan. The present report related chiefly to the *expectant plan* of treatment, which was defined as follows: "If the joint is inflamed, entire rest is ordered; if abscess form, it is opened; if loose bone be detected, it is simply removed as if it were a foreign body interfering with the process of healing; if, in the further progress of the case, malposition of the parts is found, a support or brace is given to rectify the deformity."

The cases reported were furnished by Drs. V. P. Gibney, James L. Little, Reid and Blauvelt, and Dr. Satterthwaite. Two cases were omitted from the classification, because suppuration never occurred at any time in their course, and the disease underwent spontaneous resolution. After giving a sketch of each case, the following summary was presented: Of the twenty-two cases there was undoubted suppuration with caries or necrosis, or both, involving the bones of the tarsus or articular extremities of the tibia or fibula, or severally or combined. In two cases the patients died while under treatment; one from unknown causes, the other from disease disconnected from the joint affection. In four cases suppuration still persisted, but all were steadily improving. In fourteen cases the expectant plan was adopted, and all the patients had useful joints. The duration of suppuration varied from five or six months to five and a half years. Of the two remaining cases, one was treated mainly by extension; suppuration ensued only when the brace had been temporarily removed, but the final result was a useful joint in a little over two years. The committee were of the impression that caries of the joint must be studied apart from other joint troubles. In children, certainly, no matter how cachectic they were, the expectant plan would, if persevered in, in the great majority of cases accomplish a cure without subjecting the patients to the dangers of any such internal complications as tuberculosis or waxy change in the kidneys.

DR. V. P. GIBNEY referred to points which might be added to the report. The *first* related to *good results* from expectant treatment of caries of the bones in and about the ankle-joint in childhood. With reference to the treatment of such cases in adult life they had no data.

The *second* related to the *less frequent occurrence of amyloid degeneration* in connection with chronic suppurative disease of the ankle-joint than of other joints. In nearly fifty cases of caries of the ankle-joint, which had been under his observation, he had not seen one which terminated in amyloid degeneration of the liver and kidneys, as occurred in cases of prolonged suppurative disease about the hip and knee-joints. He thought surgeons might feel well assured that, in waiting for the processes of cure by the expectant plan, they need have no fear of amyloid degeneration, as in connection with chronic suppuration of other joints.

So far as treatment and prognosis were concerned, they were practically the same, whether the disease involved the ankle joint or other articulations about the joint. It was not possible, always, to make nice distinctions and locate the disease in this or that bone in that region. With regard to atrophy of the limb, he knew of only one case in which it had not remained as a permanent condition.

With regard to the pathology of the disease, he believed it to be an osteitis primarily; that sprains and falls were sequences, as a rule.

There was a difference between a perfect joint and a useful joint. If the term perfect joint was used in its strict sense it might lead to erroneous conclusions. In most of the cases which he had seen, the patients had recovered with useful joints, but there was always some imperfection of the joint which was permanent. He had never seen any cases which could have been regarded as perfect cures—that is, cures with absolutely perfect joints.

DR. F. A. CASTLE thought the conclusion regarding amyloid degeneration worthy of further consideration, and asked if the committee had been able to determine why suppuration of the ankle-joint should not be followed by that change the same as was suppuration of other joints.

DR. E. C. SEGUIN asked if the treatment in the cases reported had been conducted under antiseptic precautions. He also asked if there was a diminution in the faradic reaction of the muscles?

DR. SATTERTHWAITE replied that antiseptic precautions were not adopted, the only precaution taken being the use of a plaster-of-Paris splint in one or two of his own cases with fenestræ, to permit the passage of the oakum rope which was drawn through the diseased joint.

He further remarked that, as a rule, there was not much discharge in chronic disease of the ankle-joint, and, perhaps, that fact might have some bearing upon the question of amyloid degeneration. His conviction was, that considerable suppuration was necessary to the production of amyloid degeneration, and, besides, the suppuration in ankle-joint disease commonly had less duration than that dependent upon disease of other joints. The *average* duration of the discharge in the cases reported could be reckoned by months, whereas the *average* duration of suppuration in other diseased joints was, doubtless, much longer. The committee had no data relating to electrical reaction.

THE PRESIDENT said that he had, in a number of cases, applied the galvanic current, and had found that, when the swelling was very great, the galvanic irritability was diminished. He had explained the diminution by the simple fact that there was an unusual changed condition of all the tissues, and whenever the current had to go through different tissues it was weakened, therefore the reaction apparently diminished. But in cases in which the disease was inactive, only slight in amount, or was nearly cured, he had not found a difference with regard to

electrical reactions in the sound and the diseased limbs.

One reason why so little amyloid degeneration occurred in connection with chronic disease of the ankle-joint, might be found in the fact that, as a rule, the suppuration was superficial; if abscess formed, its contents were easily thrown off. Changes in distant organs were more likely to occur when bones were attacked by disease in or near their centres, where blood-vessels were numerous, large, and remained open. The process about the ankle-joint was not of that description: it was a caries, not a necrosis, and the blood-vessels did not remain open, and whatever pus existed was not liable to be pressed into the circulation as it was in disease of the more compact bones, and affected nearer their centres.

He accepted the expectant plan of treatment according to the definition given by the committee.

PHOSPHORUS IN SUBSTANCE AS AN AGENT IN THE NEW FORMATION OF OSSEOUS TISSUE.

He had for a long time treated such diseases, particularly caries of the ankle-joint, by the internal administration of *phosphorus in substance* for the purpose of facilitating the formation of bone. The effect of the phosphate of lime in that direction was a rather doubtful one; investigations relating to that question were not fully closed. Whenever phosphate of lime was administered, it at once appeared in the urine in large quantity, and it was, therefore, not quite plain how the administration of phosphates could contribute materially to the formation of new bone. But with phosphorus in substance it was different. Some seven or eight years ago he began the treatment of the class of affections under consideration by the use of phosphorus in substance, in accordance with hints given and results obtained experimentally by Wegner of Berlin, who fed a certain number of rabbits with minute doses of phosphorus, and found that fractures were united in a much shorter time than in other rabbits that received no phosphorus, and that the result was obtained uniformly. In cases, therefore, in which it was desirable to increase the amount of bone thrown out from the periosteum—for example, in rachitis, and also in carious disease of bones—he adopted the expectant plan defined by the committee, and gave phosphorus in substance from the beginning, and he was positive that a large number of cases had recovered in the course of four to six months, at farthest, within one year from the time the treatment was begun. The phosphorus should be given before and after suppuration had begun, and he thought it deserved much more attention than it had yet received. The average dose was from $\frac{1}{100}$ to $\frac{1}{100}$ of a grain, three times a day, dissolved in oil.

It was not adapted to acute, but to subacute or chronic bone diseases, and was applicable in incipient Pott's disease.

Dr. Mary Putnam-Jacobi referred to cases of excision of the elbow-joint, in which the phosphorus treatment was adopted, and they were entirely healed within six months after the operation.

The Society then adjourned.

The Lettsomian Lectures for the present season, before the Medical Society of London, are to be delivered by Mr. W. F. Tevan. Subject: "The Treatment of Stricture of the Urethra, Enlarged Prostate, and Stone in the Bladder, with Special Reference to Recent Progress."

WEST CHICAGO MEDICAL SOCIETY.

Regular Meeting, November 24, 1879.

The Secretary read a paper written by Drs. Christian Fenger and J. H. Salisbury, on

DIFFUSE MULTIPLE CAPILLARY FAT EMBOLISM OF THE LUNGS AND BRAIN AS A FATAL COMPLICATION IN COMMON FRACTURES, ILLUSTRATED BY A CASE.

A woman, 45 years old, had received a fracture of the left femur, through the upper part of the shaft. The next day after the injury the patient was restless, but did not suffer much pain. Next day the respiration became hurried and the patient was noticed in the morning to be sleeping in the afternoon the sleep appeared to be a sort of coma, from which it was difficult to rouse her. The pupils responded to light. Toward evening slight spasm occurred; at 7 P.M., the pulse was 112, and weak; temperature, 101¼° F.; respiration 40, and regular; the coma constant; the face pale, and lips bluish. The thorax moved naturally.

Auscultation showed the heart-sounds to be natural, and the presence of the normal vesicular breathing; no râles were heard.

The day following, the symptoms showed little change, except the presence of coarse râles in the chest. Dr. Fenger made the diagnosis of fat embolism of the lung; prognosis fatal.

She died the same day.

Dr. Salisbury noticed about the patient an indescribable sweetish odor.

An autopsy made twenty hours after death. In the pericardium was about half an ounce of thin, yellow fluid. The heart was flabby, and its muscle grayish; the heart and large vessels contained dark fluid blood, as in strangulation. Small drops of fat were swimming on the blood. In the subpleural tissue were small ecchymoses, some as large as a pin's head. The whole surface of the left lung had a peculiar red, spotted appearance, most anteriorly; the cut surface of the lung had a similar appearance. "Some parts were quite white, which was due partly to anæmia, but chiefly to emphysema along the anterior borders." The posterior part of both lungs was congested and œdematous, but there was no capillary bronchitis. At the base of the right lung were several large ecchymoses, mostly subpleural.

The large ventricles of the brain contained a little clear, serous fluid.

"On the cut surface of the hemispheres, especially in the white substance," were numerous ecchymoses, "small, round, dark blood-red points," the largest a millimetre in diameter. These were found throughout the white substance and somewhat in the gray. Similar spots were discovered in the cerebellum, in the anterior part of the pons varolii and corpus callosum. The cerebral vessels were normal.

On the surface of the spleen, which was not enlarged, were several superficial hemorrhages of one-sixth inch in diameter. In the fundus of the stomach were several small ecchymoses.

A transverse fracture of the upper part of the left femur was found, surrounded with coagulated blood, which filled the intermuscular spaces. The substance of the fractured bone was normal. The marrow of the shaft was yellow from infiltration of fat, as was usual in old people. There was no evidence of inflammation, nor were there coagula in the large veins in the neighborhood. Dark fluid blood filled

the femoral vein, in which no fat-drops were discoverable.

Examination with the microscope showed that, in pieces cut from the surface of the lung the small arteries and some capillaries of the pleural tissue appeared as a whitish yellow refracting network from being full of liquid fat. Tissue from the interior of the lungs showed a "fine, more or less complete injection of liquid fat in the network of capillaries surrounding and protruding into the air cells."

Examination of the ecchymoses in the brain showed the small arteries and their centres to be filled with liquid fat. In none of the other organs of the body was fat discoverable in the smaller vessels.

The first notice of the danger that fat from the marrow of bones may find its way into the blood-vessels in extensive fractures was by Prof. Trenker, in Germany, in 1862. Since then it had been found that fat embolisms of the lungs occurred in almost every case of extensive fracture. It was the rare exception, however, for the fat to be present in such quantity as to give rise to serious disturbance. It had been found in Strasbourg that slight diffuse fatty embolism was present in "ten per cent. of a series of 250 dead bodies."

Sinclair had studied 140 reported cases, and found the embolisms to be due to extensive contusion of soft parts containing an abundance of adipose tissue, to fractures with extensive lesion of marrow of the bones, or to osteomyelitis. The most severe cases were due to fracture.

The symptoms of the complication, as Sinclair gave them, were: unexpected rapidly increasing general debility; then symptoms of non-aëration of the blood; rapid respiration (40 to 60 per minute); weak and rapid pulse; râles in large bronchi; dyspnœa and sometimes reddish foam emitted from the mouth. The patients grow pale, cyanotic, cold; coma comes on, and death, sometimes preceded by vomiting and spasms.

It was not uncommon to find thrombosis of the larger veins around a fracture; thrombi always formed in the smaller veins, causing, probably to some degree, the œdema so common. From this came, in a very few cases, embolism of the lungs; but this always occurred, if at all, later than forty-eight hours after the injury.

In a large number of cases of fatty embolism death had occurred suddenly, and in a larger number of cases within twenty-four hours.

The prognosis in such cases would depend upon the amount of fat in the vessels and upon the strength of the heart's action.

The treatment should be stimulative, in the hope that the heart might force the fat through the capillaries. The fractured ends of bone should be kept still to prevent rupture of the fat sacs and the marrow, and the entrance of the fat into the vessels.

Microscopic slides of the lung in this case were exhibited, showing vessels filled with fat.

After some discussion of the case, the Society adjourned.

WHO FIRST DISTINGUISHED TYPHUS FROM TYPHOID FEVER?—A discussion is going on in England as to who was the first to appreciate and teach the above distinction. Priority is claimed for Mr. A. P. Stewart and Dr. John Reid, on the one hand, and for Dr. Robert Perry, of Glasgow, on the other.

The evidence is rather in favor of the latter, who taught the new views in 1836–37.

ABSTRACTS OF FOREIGN SOCIETIES.

BRITISH.

CLINICAL SOCIETY OF LONDON

DECEMBER 12, 1879. E. H. GRIESINGER, M.D., F.R.S., PRESIDENT.

Analysis of Forty-five Cases of Excision of the Hip-Joint.—MR. CHURT prefaced his remarks by stating that the operation could be made more successful, when it was performed before abscesses had opened, than later. The result of his analysis showed that, in forty-five operations which had been performed, eighteen cases were cured; nine patients were relieved, but had died from causes not due to the operation; eleven were still under treatment or observation; one died from diphtheria; six had died from causes either directly or indirectly referable to the operation. In fourteen patients the joints were movable, and could be flexed or extended; in nine the affected limb could be adducted and abducted to a certain degree, and flexion could be performed to a considerable extent; in four of the cases the patient could stand firmly and steadily on the limb without assistance. In all the cases the limb was straight, and there was no permanent flexion of the pelvis. The patient could stand erect, and without any curving of the spine. The causes of death directly referable to the operation were as follows: three from pyæmia; one from septicæmia, and one after suppuration in the bone following erysipelas. If fluid was present in or about the joint, accompanied by starting pains, an incision should be made; and if struinous disease or necrosis was found to be present, excision should be performed. The causes of failure were: delay in operating; not removing enough of the diseased parts; not allowing a free exit for the discharge of pus, etc.; and not operating antiseptically.

A New Method of Excising the Hip-Joint.—MR. R. W. PARKER described the following method of performing excision at the hip-joint. An incision is made from the anterior superior spine of the ilium downward, along the anterior border of the great trochanter, cutting between the sartorius and rectus muscles on the inner side, and tensor and glutei on the outer side. The diseased bone is sawn off *in situ*, and then extracted with a sequestrum forceps. The key-hole saw is used, so that the periosteum and adjacent structures may not be injured. One advantage claimed for the operation is that cutting across the large muscles attached to the great trochanter is avoided. He believed that an exploratory incision should be made into the joint, when the disease had progressed for three months whilst under treatment, and signs of destruction of the joint had made their appearance. If this plan were adopted he thought that more satisfactory results would follow from operating.

In the discussion which followed, MR. HOLMES said that he did not believe that the best plan of treatment of abscesses in the vicinity of joints was to lay them open antiseptically; he preferred waiting until there was sufficient evidence of destruction of the cartilage. He did not believe that a patient could stand on the leg after excision of the joint, as there was too much mobility. MR. HULKE thought that, if the local disease was in an advanced stage and the patient was in good health, excision was expedient; but, if it were in the earlier stages of the disease and the patient was losing strength, the operation

should not be performed. He advocated the use of chloride of zinc for washing out the cavity, as did Mr. Lister, who followed with some remarks. In excising at the hip-joint, Mr. Morrant Baker always cuts through the neck of the femur and leaves the trochanter, as by so doing the limb is stronger. He said that a perfect result was not always obtainable, and that a great deal depended upon the selection of proper cases to operate on.

MEDICAL SOCIETY OF LONDON.

Stated Meeting, December 15, 1879. Dr. Cockle, President, in the Chair.

Contamination of Atmospheric Air by Arsenical Pigments.—Mr. W. Foster read a very interesting paper on the above subject. Dry Scheele's green, heated to 50° C., was subjected to a current of atmospheric air. The air, after being filtered through cotton wool, was passed through a caustic potash solution. When examined by Marsh's test, the potash solution was found to be free from arsenic. Deal-shavings coated with paint composed of Scheele's green, linseed oil, and turpentine, were placed in a vessel, and a current of atmospheric air passed through for a number of days. After passing the air through two bulb-tubes—one containing nitrate of silver in solution, the other a caustic potash solution—an examination was made, and no arsenic found. These experiments tend to show that dry Scheele's green does not give off arsenic at ordinary temperatures, or that a paint of Scheele's green, in the process of drying, gives off arseniuretted hydrogen. Contamination of the atmospheric air with dust from pigments containing arsenic, has connection with the foregoing subject. Dr. Ewart thought that arsenical poisoning might be due either to sewer-gas, or other gases, proceeding from houses in which such paints or fabrics were used. Mr. Foster could not agree with Sir J. Favrer that arsenically tinted chintzes were innocuous. He believed that poisoning produced by these fabrics was caused by a detachment of the actual particles of the pigment.

Œdema of the Glottis.—Dr. De Havilland Hall presented the following history of a case seen by Dr. Lowe. The patient, a boy five years, was well up to the morning of the day previous; he then complained of not feeling well, but went out in the afternoon and appeared as well as usual. He vomited after tea; slept well from seven in the evening until eleven; vomited twice between eleven and one; died at 1.30. On examination after death, the most prominent feature was found to be œdema of the glottis, with a deep red appearance of the posterior surface of the epiglottis and mucous membrane of the larynx; there was a distinct circumscribed hemorrhage into the submucous tissue of the posterior wall of the larynx, from the level of the left false vocal cord to the upper edge of the incised cartilage. The pupils were dilated slightly, face and neck greatly congested, and a yellow colored fluid oozed from the mouth. The most remarkable feature of the case was the absence of perceptible dyspnœa and cough, the death being attributed to spasm of the glottis, caused by entrance of vomited fluid into the larynx. Dr. Dowse thought that the symptoms were due either to scarlet fever or some malignant poison, he having seen similar cases to the one described.

PATHOLOGICAL SOCIETY OF DUBLIN.

Saturday, December 6, 1879. E. H. Bennett, M.D., President, in the Chair.

Multiple Pyæmic Abscess of the Right Lung and Liver.—Dr. Walter G. Smith described a case and presented the viscera of a woman 45 years of age, whom he had treated at the Adelaide Hospital. The patient was a well-built woman, who had always enjoyed good health until the commencement of August, when a severe gnawing pain developed itself in the right shoulder, knee, and leg. She had not met with an injury, nor had any operation been performed on her. About the beginning of September she had an attack of dyspnœa, which increased in severity; it was unaccompanied by profuse sweating, nor were there any rigors. On physical examination rhoncus and sibilus were discovered over the right side of the chest. Pulse 150. Slight jaundice, purpuric spots over the body, and pyrexia. The line of dulness of the liver did not appear to be altered. She became delirious, and died four days after admission. On post-mortem examination, the following appearances presented themselves: left lung congested, but no consolidation or adhesions. There was consolidation of the upper lobe of the right lung, which was very friable, and broke down in detaching it from its adhesions. There was no effusion into either pleural sac, nor was there any sign of peritonitis. The heart was small and very soft, presenting the appearance seen in fatal cases of typhus fever. Hæmorrhagic spots were to be seen in the endocardium. In the aorta, on the under surface of the mitral valves, around the coronary orifices, and in the floors of the sinuses of Valsalva, were atheromatous deposits, which did not exist on the free edges of the sigmoid valves. The liver was soft and friable, and not greatly enlarged, the surface being of a buff yellow and presenting numerous hæmorrhagic points and yellow patches, which gave it a mottled appearance. On making a section of the organ, many red consolidations were to be seen, soft in consistence and exuding a sanious fluid, brownish in hue. No ulcer of the stomach could be found, nor were there any gall-stones present.

Hypertrophy of the Heart—Hydrothorax—Cirrhosis of the Kidneys.—Dr. J. W. Moore exhibited the lungs, kidneys, heart, and part of the liver of a hodcarrier, aged 19. Both kidneys presented an extensive granular degeneration, but no history of intemperance, lead-poisoning, or gout. The heart was hypertrophied and weighed fifteen and a half ounces when freed from clots. There was dilatation of the left ventricle and of the mitral valves, but no endocarditis. There had been a mitral systolic murmur before death. There was hydrothorax and cirrhosis of the liver.

METROPOLITAN COUNTIES' BRANCH: SOUTH LONDON DISTRICT.

Wednesday, October 22, 1879. S. O. Habershon, M.D., Chairman.

On the Employment of Double Extension in Cases of Disease and Injury of the Spine and Pelvic Joints.—Mr. John Wood said that the following benefits resulted from the application of extension in the treatment of joint diseases: 1. Absolute rest, preventing the muscles from acting; 2. Removal of pressure on the surfaces of the joints; 3. Prevention of displacement by muscular action; 4. Removal of tension and

demonstration of irritation of the nerves. He found that Beck's plan of counter-extension, by means of a stirrup applied by adhesive plaster, produced an unequal action of the muscles of the spine, as the extending force acted in a one-sided manner. To overcome this objection, he was in the habit of applying weights to both limbs, and causing double extension. He had made use of double extension both in sacro-iliac joint disease and in disease of the lower dorsal and upper lumbar vertebræ, with good results.

Pneumonia of the Apex of the Lung.—Dr F. T. Roberts read a paper on the above subject, in which the following were enumerated as the causes of the disease: 1. As a result of direct injury from fracture of the upper ribs. 2. From extension of inflammation from the lower to the upper lobe. 3. Secondary to phthisical diseases affecting the apex of the lung. 4. In connection with the pleuritic effusion, and, perhaps, with other conditions causing condensation of the lung tissue. 5. In consequence of hemorrhage into the upper part of the lung. 6. As a primary or idiopathic affection. He believed that nature would do a great deal toward accomplishing a cure, and advised cessation from work, quinine, and counter-irritation by means of small blisters and iodine. Dr. F. Taylor said that he had met with the disease more frequently in children and in connection with measles.

FRENCH.

ACADEMY OF MEDICINE.

DECEMBER 23, 1879. M. Richet, Presiding.

Local Vacations of Temperature in Disease.—M. Peter read a paper in support of his claim to priority in pointing out the local variations of temperature in disease. The subject of local abnormal temperatures began to occupy his attention in 1864, and the results of his observations were published in the following year. Since then he has published several articles on this subject, the last of which was noticed in The Record for Jan. 17th. While insisting on his right to the credit of priority in this matter, M. Peter does justice to the valuable labors of Dr. E. Seguin in the same field of inquiry.

M. Colin read a paper entitled *Experimental Researches in the Mode of Development of Passive Dropsies.* The following are his conclusions: When the venous circulation in animals is obstructed by mechanical obstacles, œdema or dropsy is produced as soon as the pressure exerted by the vascular walls on the blood-column is raised to the maximum point. Ligature, compression, or partial obliteration of a vein, gives rise to œdema or to some form of serous effusion, whenever collateral vessels are not able to carry off a sufficient proportion of the blood. Ligature of the jugular causes infiltration in animals which have only one vein on each side of the neck, and not in those which are provided with a deep vein accompanying the carotid. The same is true of the saphenous and the superficial veins. The lymphatics may undoubtedly play an auxiliary rôle in the genesis of partial infiltrations, if a large number of them are compressed by tumors or by inflammatory exudations, or if a morbid condition of the glands renders them partially impermeable to the lymph. The lymphatics may also contribute to the development of general infiltrations, when the thoracic duct is compressed, or is obstructed by clots derived from blood that has been forced into the duct by the violent reflux attendant on cardiac affections. The vaso-motor nerves do not seem to take any decided part in the production of passive dropsies. The vascular paralysis caused by section of these nerves does not sensibly favor the exhalation of the serosity of the cellular tissue when it is combined with hesitation of the veins. Moreover, it never causes infiltration when its action is isolated and independent of mechanical obstacles to the venous circulation.

SOCIETY OF SURGERY

DECEMBER 10, 1879. M. Tarnier, Presiding.

Elytrorrhaphy for Prolapsus.—M. Panas read a report on a specimen presented at the last meeting by M. Zancarol. The case was one of elytrorrhaphy performed according to M. Le Fort's plan for complete and consumed incurable prolapsus of seven years' standing. The patient, a woman thirty-six years of age, had been confined three times; the prolapsus, which was complicated by rupture of the perineum, dated from the last labor. M. Zancarol made two lateral vaginæ by uniting the anterior and posterior vaginal walls in the median line. He introduced twelve points of suture—five on each side, one at the internal, and one at the external end of the denuded surface. The womb was replaced gradually as each point of suture was introduced. This is the third case of this operation of which the results have been reported; the other two were reported by M. Le Fort and M. Panas. In this case the success was perfect; the patient died suddenly twenty-eight months after the operation, and M. Zancarol was fortunate enough to obtain the specimen. Seven months after the first operation, he had performed perineorrhaphy to correct a slight rectocele. M. Panas claimed that M. Le Fort's operation gives excellent results, and remedies effectually a very grave infirmity. The sole objection to it is that, as a rule, it is only applicable to women of advanced age, who cannot hope to become pregnant again. In view of the difficulties presented in the removal of the sutures, he recommended the use of catgut sutures.

M. Tillaux said that carbolized silk would be even better than catgut, as it is more supple and stronger, and is absorbed almost as readily.

DECEMBER 24, 1879. M. Tarnier, Presiding.

M. Dezanneau reported *fifteen cases of ovariotomy* performed by himself. Four of the patients died—two from peritonitis, and two from depression of the vital forces and shock. He insisted on the importance of always directing the instrument against the tumor in separating adhesions. He is disposed to follow the example of those surgeons who leave the pedicle in the abdominal cavity. As a preventive of peritonitis, he recommended absolute immobility. In cases where meteorism was troublesome, puncture of the stomach and intestines had given him excellent results. He preferred a small external incision, as recommended by Spencer Wells and Koeberle.

M. Duplay criticised one of the manipulations employed by the reporter, viz.: the introduction of the hand into the cavity of the cyst to break up the partitions between the secondary cavities. He claimed that this practice is liable to give rise to severe hemorrhages.

M. Tillaux stated that he had removed during the year two enormous cysts, and that he had been compelled, in both cases, to introduce his hand into the cyst to break up the various partitions. He had no hemorrhage in either case.

M. Gillette thought that puncture of the stomach, to relieve pneumatosis, was not an entirely innocuous operation. He prefers to use the œsophageal sound.

Correspondence.

THE SIZE OF THE BLOOD-CORPUSCLE.

War Department, Surgeon-General's Office,
Washington, D. C., Jan. 19, 1880.

To the Editor of The Medical Record.

Dear Sir:—Your excellent journal, of which I have long been a reader, has always appeared to me to manifest such fairness in its editorial department that I cannot for a moment believe that it was your intention to misrepresent me in the editorial of January 10th, entitled "Further Expert Testimony at the Hayden Trial;" and yet you have actually done so by making use of the newspaper reports of my testimony in that case, in which, as is usual with newspaper reports of scientific testimony, there are a number of inaccuracies, and erroneous impressions are made as to several matters by the presentation of single sentences without the context. Will you not, therefore, as a matter of justice, give equal publicity to the following brief corrections and a few words of explanation?

You write: "Dr. Woodward testified that the size of human blood-corpuscles in different persons was as variable as that of the individual; and the size also varied greatly even in the same animal." What I actually testified as to these points was substantially as follows: That the largest human corpuscle I had ever measured in any individual, including all ages, was 400 millionths ($\frac{1}{2500}$) of an inch in diameter, the smallest 222 millionths ($\frac{1}{450}$). I said that I did not, however, for a moment believe that these dimensions represented the extreme limits, for G. Hayem (Rech. sur l'anat. normale et path. du sang, Paris, 1878, p. 44) has recently affirmed that in chronic anæmic conditions he has measured them as large as 12 or even 14 micromillimetres (the latter = 551 millionths of an inch), and as small as 2.5 or even 2.2 micromillimetres (the latter = 86 millionths of an inch). But, even taking the limits I had myself measured as the extremes for healthy individuals, the difference in size between the largest and the smallest human blood-corpuscles was about as great relatively as the difference between the shortest and the tallest adult man; and as in both cases all possible intermediate sizes occur, I held that we are no more likely, by measuring ten, or fifty, or a hundred, or even a much larger number of corpuscles, to obtain an average size that will agree with the next set of similar measurements, than we are by measuring the height of as many men likely to obtain an average which will agree with the average height of as many more individuals measured elsewhere.

It was to this cause chiefly that I attributed the considerable differences between the statements as to the average size of the human red corpuscles published by the highest microscopical authorities during the last few years. You make me say: "The most recent authoritative measurements made the average diameter $\frac{1}{3500}$ of an inch." What I really said was, that while many English and American microscopists continued to assume the infallibility of the alleged average size of 312 millionths ($\frac{1}{3200}$) of an inch, propounded by Gulliver in 1848, such able French microscopists as Cornil and Ranvier (Manual d'histologie pathologique, Part II., Paris, 1873, p. 498) placed it as low as 7 micromillimetres (*i. e.*, 275 millionths, or $\frac{1}{3630}$ of an inch). The commission of the French Société de Médecine Légale (Annales d'hygiène publique, T. 40, 1873, p. 194), composed of Messrs. Miahle, Mayet, Lefort, and Cornil, which reported, June 9, 1873, placed it at 7.5 micromillimetres (*i. e.*, 295 millionths, or $\frac{1}{3390}$ of an inch), with which Hayem (p. 43, op. cit. *supra*) and other recent French authorities agree. On the other hand, J. Pelouze and E. Frémy (Traité de chimie, etc., 3me éd. entièrement refondu, T. VI., Paris, 1865, p. 492) place the average as high as $\frac{1}{2500}$ of a millimetre (*i. e.*, 328 millionths, or $\frac{1}{3050}$ of an inch), while the average usually accepted in Germany, that of Welcker (Zeitschr. für rat. Med., Bd. xx., 1863, S. 257), is intermediate between the foregoing, viz., 7.74 micromillimetres (*i. e.*, 304 millionths, or $\frac{1}{3289}$ of an inch).

As for myself, I did not pretend to make any general statement as to the true average size of the human red corpuscles, my experience being that the averages obtained by the most careful measurements of any moderate number of corpuscles differ considerably. As to this, I cited the figures I have published (Amer. Jour. of Med. Sci., January, 1875, p. 151, and Trans. of the Amer. Ass'n, vol. xxvii., 1876, p. 303), and added that several other average measurements of human blood recently made by me with every possible precaution also differed from each other considerably (as will be seen below).

As to the red blood-corpuscles of the dog, I testified that I had measured in this animal single corpuscles as large as the largest I have ever myself measured in human blood, others as small as the smallest in human blood, and every possible intermediate size. Here, too, on taking averages, I had arrived at variable results, as Gulliver himself did long ago. I explicitly stated that the general average of all the measurements I had ever recorded for the dog was somewhat smaller than the average of all I had recorded for man. Yet some of the averages I had found for fifty or a hundred, or even more, canine corpuscles were larger than the smaller averages obtained for human blood; indeed, occasionally rivalled the larger. I mentioned further that I agreed with the view of L. Périer (Bull. des travaux de la Soc. de Pharm. de Bordeaux, 1877, p. 282 et seq.) that the blood of quite young dogs (up to a month or two old) more frequently contained very large corpuscles, and gave averages equal to those obtained from human blood, than was the case with older animals. I had, since the trial commenced, mounted several slides of the blood of a pup three weeks old, in which corpuscles measuring 400 millionths ($\frac{1}{2500}$) of an inch in diameter were by no means rare. (I may add that I have these slides, and will take pleasure in showing such corpuscles to any competent microscopist.) Fifty corpuscles on one of these slides gave an average of 326 millionths of an inch; forty corpuscles on a slide from another pup of the same age gave an average of 320 millionths of an inch; while twenty corpuscles from the blood of a full-grown dog gave an average of but 300 millionths of an inch. Measured with the same instruments, fifty corpuscles of my own blood gave an average of 324 millionths; forty, from another individual, gave an average of 327 millionths; twenty, from another, gave an average of 316 millionths. I added that all these measurements were made with a new Zeiss homogeneous immersion $\frac{1}{18}$ and a cobweb micrometer, the power being such that each division of the micrometer-wheel equalled $\frac{1}{7500}$ of an inch. Every corpuscle in the group selected was measured, each being first brought to the centre of the field for

the purpose, and those corpuscles which appeared to be rather more than perfectly spherical were measured in the long and short diameters, and the mean taken. In short, every known precaution was employed to secure accuracy.

In view of all the foregoing considerations, I did not think the microscope put it warranted in attempting to distinguish on oath between human and canine blood, even on preparations carefully made from fresh blood. If he makes a guess based on the average size of fifty or a hundred corpuscles, he will, no doubt, often come out right; but he will also occasionally come out entirely wrong, and the difficulties in the case of corpuscles soaked out from dried stains are of course still greater.

You remark: "Dr Woodward took in general a very pessimistic view of micrometry;" and again: "The impression given by Dr Woodward as to the exceeding vagueness and inaccuracy of microscopic measurements was unjustifiably strong." I do not think, Mr. Editor, you would have made either remark had you heard what I actually said. I pointed out, it is true, several important sources of error that would lead to very mistaken results, if neglected, besides the differences between micrometers, on which you very properly insist; but I also expressed the opinion that if every precaution *was* taken, the size of each individual corpuscle measured could be obtained with our best modern resources to within two or three millionths of an inch, which, I may note here, is about as close as Professors E. W. Morley and W. A. Rogers (Proceedings of the American Academy of Arts and Sciences, 1878, p. 164 et seq.) found it possible to measure the distances between sharply-defined ruled lines on glass. What I did express doubts about was the significance of averages taken from the measurements of comparatively small numbers of bodies so variable in size as blood-corpuscles are. And, indeed, I may say here that I am glad to admit, nay, I go further, I insist, that micrometry has considerably advanced since the days when Gulliver fixed the $\frac{1}{44}$ of an inch as the average size of the red corpuscles of human blood, and Kölliker asserted that ninety-five per cent. of those corpuscles are of the same size. (By the way, Kölliker also stated that the average diameter of the red corpuscles was $\frac{1}{140}$ of a Paris line, *i. e.*, 296 millionths of an inch. Manual of Human Mic. Anat., London, 1860, p. 519.)

Finally, Mr. Editor, let me express my satisfaction that in concluding your article you express your disbelief in the possibility of being able to distinguish human blood "in any particular case with sufficient certainty to swear away a life." With this, at least, I heartily agree, and I may say that it is my intention as soon as practicable to publish such additional details with regard to this matter as I trust will lead to more general acceptance of that sound view.

Very respectfully, your obedient servant,

J. J. Woodward,
Surgeon U. S. Army.

Dr. B. W. Richardson's Embarrassment.—By the will of Sir Walter Trevelyan, a large amount of wine was bequeathed to Dr. B. W. Richardson, with directions that it be used for scientific purposes. Dr. R. is a strict teetotaller himself, and finds it difficult to dispose of the wine in any way that will not violate the wishes of the testator or his own principles. It is expected that the hospitals will be the recipients of it.

LUNACY REFORM

To the Editor of The Medical Record.

Dear Sir:—It has been a matter of gratification to me, as I have no doubt that it has also been to my colleagues interested with me in our present movement, to perceive that you are in accord with the committee of the Neurological Society in regard to asylum abuses, notwithstanding there may be differences of opinion between us on minor points. Your editorial of the 17th ult. expresses our views quite accurately. In it you state very properly that our asylums are too often large and overcrowded, or consist of county poor-houses or wretched local institutions, in which the attendance and diet are of the most miserable order; that the number of assistants is too small, and their training frequently inadequate; that there is frequently a lack of proper appliances; that there is too much mechanical restraint, too little exercise, amusement, or employment, too much herding of acute and chronic cases; that few institutions are capable of doing good pathological work; finally, that, to employ your precise words, "clinical and didactic instruction in insanity is at its lowest possible ebb, and it is for this reason, in part, that so little attention or interest can be aroused among medical men on the subject of lunacy reform." You then go on to recommend that the objects of the present movement should be the erection of smaller asylums, capable of holding 250 or 300 patients, with an efficient visiting staff, and trained nurses in sufficient numbers to render restraint a rarity; that the medical staff should be fuller, better paid, and better qualified; that the acute and chronic insane should be treated apart; and that "the clinical and pathological material should be utilized as much as possible for the benefit of students and physicians." These are exactly our views, Mr. Editor. Place this editorial side by side with the petition to the legislature, and you will find that you have framed in your own language the same thoughts that have been given voice in that petition. I regard this as a fortunate coincidence, for it is a happy demonstration of how earnest men, differing widely in their methods, have yet been forced to identical conclusions concerning the present asylum management. From personal knowledge of asylums, from conversations with medical *attachés* of asylums, from such public sources of information as reports of medical officers and newspaper articles, as well as from our knowledge as neurologists that but scanty pathological and clinical work was being done in our costly institutions, we had become convinced, as you have become convinced, that great defects existed in our present asylum system, and that it was high time these faults should be rectified. For divers and various reasons the inauguration of a movement of reform was not to be expected from the superintendents. Against these gentlemen personally I have nothing to allege, and I know that there are those among them at whom no one can cavil—men who are honestly desirous of improvement, conscientious, well-informed, and laborious; but even the best must be hampered necessarily by their position. They hold their places on tenures that are partially or entirely political, and as they are usually cut off from private practice, they depend mainly or entirely upon these places for a livelihood. Under such circumstances men are not likely to sacrifice themselves. Upon whom, then, was to devolve the uninviting task of setting in motion a movement of reform? The New York Neurological Society took it upon itself to

perform the duty, and with eminent propriety. The New York Neurological Society is the only neurological society in the United States, with the single exception of the American Neurological Association, which meets, however, only once yearly, and is therefore not a body to guide an undertaking of this sort. The active members of the New York Neurological Society are men who have made special study of neurology, as the word is used in its proper sense to mean disease *of all nervous organs*, including insanity, which, as you and your readers do not need to be told, is as much a disease of the brain as apoplexy or meningitis. Were they not, therefore, a proper association to take charge of the matter? Every man of just mind cannot but assent. The society thereupon set to work to attack the system. It has never had it in its purview to attack men, especially those who were not responsible for the system. At meeting after meeting of the committee the opinion has been repeatedly and strongly expressed that personalities should be rigidly eschewed, except when it was necessary to mention names to substantiate facts or repel personal attacks. A petition to the legislature was gotten up, praying that an inquiry might be set on foot in regard to the condition of the asylums throughout the State. It was thought best for our purposes that the superintendents should be examined under oath; and if the testimony of these gentlemen, as given in the report of the senatorial committee, be carefully read, it will be perceived that some very damaging facts were obtained in this manner regarding the imperfections of the system. How *ex parte* was the report of the senate committee, how unjust, how full of glaring misstatements, many of which could be refuted from the appended testimony, will be set forth at length in the forthcoming reply of the Neurological Society; and I shall not pause to dwell upon it here further than to say that this reply constitutes an unpleasant but unavoidable episode—unpleasant, because of the strong and personal language employed; unavoidable, because the senatorial report was so directly slanderous and misleading that we should have been tame and sapless had we not defended ourselves in a manner as vigorous as that in which we were assailed

I have offered this short and running statement of facts in order that the profession might be better acquainted with the origin and objects of the movement than it is likely to be if it lends too willing an ear to the violent and summary denunciations that are being heaped daily upon the heads of our committee. The living, essential question, about which medical men should satisfy their minds is: Are our lunatic asylums in need of reform? All doubts as to whether Dr. Smith has interested motives in this matter, or whether Dr. Brown is feeding fat an ancient grudge, or whether Dr. Jones is seeking notoriety, are entirely foreign to the issue. Admit, for the sake of argument, that interested motives, ancient grudges, desire for notoriety, are at the bottom of the matter; still, the question remains unanswered: Are our lunatic asylums in need of reform? And if it should be made manifest that they sadly need renovation—why, then, interested motives, ancient grudges, desire for notoriety, have done a work that more elevated moral qualities might be proud of. Above all things, let the profession keep the query as to the necessity or non-necessity of asylum reform prominently before its eyes. If the asylums do not need reform, let us all go home and acknowledge that we have made a mistake. If the asylums do need reform, we have a right to demand the support of the profession in our efforts. We are waging war upon a powerful system, rooted firmly in the hearts, the prejudices, and the interests of a large body of able and influential men, and protected by the political influence of both parties in the commonwealth. Thus it is, therefore, to be expected that the defence and the counter-attack should be vindictive and noisy, and tend to obscure the main points. We ask the profession simply to be just in its judgment. If the present movement is needed, it is of too grave and momentous a nature to be slurred over by personalities. It must carry within its bosom a great truth, which in this land of ours of quick intelligence and rapid diffusion of information must eventually brush aside all flippant obstacles and triumph over them. I believe that it will. As a member of the committee of the Neurological Society, as one who has had a part in the movement, as one of the signers of the petition, I am proud of what I have done; for while I have contributed my small quota in aiding what must, if successful, be of incalculable benefit to insane multitudes throughout our land and abroad, I have done no man an injury.

In conclusion, Mr. Editor, I have a proposition to make, which I hope will meet with your approval. It is that you throw open your columns to a discussion of this question. Yours is the weekly medical journal of general medicine in the metropolis; it is evident that you are impartial in this matter; and as our sense of professional propriety restrains us from publishing our views in the newspapers, it would seem that yours is peculiarly the fitting organ for our publications. Should you see fit to assent to this, I shall be happy to open the discussion by a statement of facts, and this can then be followed by letters for and against. In this way the evils can be fully canvassed, as well as the remedies for them, and the resulting benefit will be that of a free and full debate, which shall command the attention of the profession.

LANDON CARTER GRAY, M.D.

BROOKLYN, Jan. 12, 1880.

THE ORIGIN OF THE CHORDA TYMPANI NERVE.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—I am able to add an important confirmatory observation to those published by Dr. Horatio Bigelow in the RECORD, favoring the view that the chorda tympani nerve is after all not a branch of the facial proper, but the continuation of the *nervus intermedius* of Wrisberg.

It is well known that the latter nerve is entirely distinct from the facial at the origin from the medulla oblongata. In numerous transverse microscopic sections of human and animal peduncular tracts, I have found that the fibres of the nervus intermedius have *no* connection with the facial nerve nuclei. Their central termination lies, in fact, in lower altitudes—that is, while the facial nuclei are situated within the lower pons margin, the nucleus of the nerve of Wrisberg lies strictly within the limits of the medulla oblongata in the level of the superior auditory nucleus.

The gray origin of the nerve of Wrisberg is diffuse, and, in the *strict* sense of the term, cannot be called a nucleus for that reason. On examining its relations more closely, we find that it *does not correspond to the*

ventro-lateral column of the medulla, but to an ideal continuation of the gelatinous column of the trigeminus region, in other words, it originates in the *ventro-gray* column of the medulla. While this discovery, whose details I shall publish in full before long, strictly confirms Dr Bigelow's view, that the nervus intermedius and chorda tympani together constitute an entirely distinct system, and have no other than an accidental anatomical relation to the facial (as it were), it throws no light on the much-disputed question as to the part played by the *nervus intermedius* and *chorda tympani* in the function of taste; it permits us to say only, that both the former and the latter with its intracranial part of the nerve of Wrisberg originate from the sensory column of the medulla and must be both sensory or trophic nerves.

Dr. Matthias David claims to have traced the nervus intermedius to a continuation of the glosso-pharyngeal nucleus. I am not able to confirm this observation; it seems very seductive and plausible on first sight, but in so many cases has this writer made hasty and inaccurate statements that it would be well to wait for confirmation of his view from other sources before accepting it.

Dr. Edgelow makes one statement to which I must take a profound exception; he attributes the sensory function of Wrisberg's nerve to a ganglion on the nerve. It is generally conceded that peripheral ganglia are obscure in their function, and that the function of a cerebro-spinal nerve is determined by its *central* connections.

Respectfully yours,

E. C. SEITZKA, M.D.

130 EAST FIFTIETH STREET.

GRATUITOUS SERVICES TO CLERGYMEN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I wish to give you my method of practice in the families of clergymen, which I think is a good one in small towns, where only one or two clergymen and one or two doctors find a home. When my pastor asks me for his bill, I simply say that I will set his sermons against my prescriptions and call it even. I pay no pew-rent and he pays no pill-bill. Beyond ordinary practice—if I were to perform a severe surgical operation in his family, for example—I would charge him the regular fee. So, if he should officiate at my wedding or funeral let him receive the regular fee. I recommend this plan as a simple solution of the question of "Gratuitous Services to Clergymen."

Yours truly,

F. B., M.D.

PEACHAM, VT.

HIGH TEMPERATURE IN NERVOUS SHOCK.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In answer to the inquiry of A. L. C., in your last issue, I would refer him to the report of a paper read before the Clinical Society of London, by J. W. Teale, on a case of excessive temperatures following a shock to the spine from a fall, and reported in the *London Lancet* of March 6, 1875. Seven different thermometers were tested in this case, and finally a special one made on account of the want of a sufficiently high register. This, however, was only marked to 122° F., but on testing it, it rose above even this, so that Mr. Teale supposes it reached on that occasion 125°. For a number of days the range fluctuated between 116° and 122°, and for seven weeks never fell below 108°.

In justice to myself, however, I should state that I never saw or knew of the lecture on the therapeutical action of cold until I read it in the RECORD of January 31st. This article is evidently an abstract, by some gentleman, of notes on a course of four lectures delivered during the winter term by me on this subject, and in the course of which to illustrate the statement that a high thermometric range owes all its significance to the particular morbid state present but of itself may be of slight importance, I referred to this case as reaching 123° and continuing for several weeks at figures which, in disease, would presage death in a few hours. In the abstract it appears as remaining at 123° for several weeks, which I did not say.

Yours,

W. H. THOMSON.

[The lecture came to us in the regular way, through a member of the staff, and the fact that the author did not see the proof was due to an oversight of the gentleman having the matter in charge. ED.]

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 18 to January 24, 1880.

TAYLOR, M. K., Capt. and Asst. Surgeon. The leave of absence granted him from Headquarters Dept. of Texas, is extended one month. S. O. 9, Mil. Div. of the Missouri, January 19, 1880.

WORTHINGTON, J. C., 1st Lieut. and Asst. Surgeon. Relieved from duty at Ft. Grant, A. T., and assigned to duty at Ft. McDowell, A. T. S. O. 4, Dept. of Arizona, January 6, 1880.

DEATHS FROM CHLOROFORM.—A recent number of the *Lancet* alludes to another of those apparently increasing cases of death from chloroform in Europe, occurring upon the administration of this anæsthetic for comparatively trifling operations.

In the present instance, according to the report of the coroner's inquest detailed in the *Lewis Mercury* of November 21th, the anæsthetic was administered for the enucleation of a diseased eyeball. There were no unusual signs of danger, but the heart's action suddenly failed, and the man died in a few moments. The post-mortem revealed nothing to ac-

ount for the death; all the organs were found to be ealthy.

A number of cases have also been lately reported, n which death occurred within the first two minutes f administration, and which, as in this instance, either previous indications against the use of the nasthetic, premonitory indications of danger during s administration, nor explanatory post-mortem ap-earances, existed.

It is a matter of speculation to what limits the ate of deaths from chloroform may extend before ustifying an indictment for manslaughter. Certainly, o drug in the materia medica has killed so many eople—a mortality the more inexcusable, since in ther, which first established a practicable anæsthesia, he profession procures an innocuous anæsthetic. Death from chloroform, when it occurs, is unavoid-ble—from ether, avoidable; a vital difference, which eaves the conscientious surgeon but little choice.

Another death from chloroform occurred January 8th, in Somerville, N. J., in the office of Dr. H. F. Vandeveer. The patient was a boy aged five years, who was being operated upon for the removal of a piece of glass from the foot. During the operation he father, who was holding the boy, fainted, and both fell from the chair to the floor. The boy ex-pired almost immediately afterward. The anæsthet-e was administered with the usual precautions. Death was due to paralysis of the heart. The cor-oner's jury exonerated the operator.

Reception in Honor of Dr. J. Collins Warren, of Boston.—Mr. William H. S. Wood, senior partner of the firm of William Wood & Co., Medical Publishers, gave a reception January 22d, at his new residence in Sixty-third Street, in honor of Dr. J. Collins War-ren, of Boston. A large number of representative medical men of this city were present, and the occa-sion was in every respect an enjoyable one.

Anti-Vivisection Movement.—A petition is circu-lating in this city against the bill recently introduced to prevent vivisection. It is presented to medical men only, and they have, with but two or three ex-ceptions, all signed it. Prof. John C. Dalton has been most active in setting this movement on foot.

Body-Snatching at Richmond.—A number of cases of body-snatching, in or about Richmond, have oc-curred lately and have been the subject of much sen-sational talk and writing. Virginia has never provided by law dissecting material for its two colleges; hence the present trouble. According to the *Virginia Medi-cal Monthly*, there have been no cases in which the bodies of those who had friends were taken. The talk that has been occasioned was indiscreet and un-necessary.

Death of Surgeon-General J. Winthrop Taylor.—Dr. J. Winthrop Taylor, ex-Surgeon-General, U. S. N., died in Boston, January 9, 1880. He was born in this State, and entered the Navy as Assistant Surgeon March 7, 1838, being appointed from New Jersey. He was for five years with the West India Squadron, and then was on duty in home ports or the Home Squadron until the breaking out of the rebellion. He was appointed Surgeon May 1, 1852. With the exception of two years—1864–66—at Boston, most of his services during the civil war was in the Gulf. Since 1873 he has been attached to the Naval Ren-dezvous at Boston.

Rise in the Price of Quinine.—Owing probably to speculative operations, the price of quinine suddenly rose fifty cents about the middle of last month. This brought it up to $3.20 per ounce for American qui-nine. The foreign quinine is a little cheaper.

New York City's Defective Sewers.—Recent complaints have brought to light the great deficien-cies in the sewers of this city. There are 370 miles of sewers altogether. Of this, 205 miles are built on the old fashioned plan. They are laid without much regard to the natural watercourses, and, in part, are composed of clay-pipes, or are simply drains open at the bottom with stone sides uncemented. About one-third of the streets above Twenty-first Street are drained with clay-pipes. These are liable to be crushed in and thus stop the sewage flow. Such an accident recently occurred in Fifty-sixth Street. As a result, a large amount of sickness has occurred in that vicinity of late.

The Metric System and Congress.—The House Committee on Coinage, Weights, and Measures, Jan-uary 27th agreed to report favorably a bill authoriz-ing importers to use the metric system of weights and measures. They also agreed to report favorably several bills providing for the adoption of the new metric gold and silver United States standard coins as formulated by Dr. W. W. Hubbell for international purposes.

St. Michael's Hospital, Newark, N. J., and the Resignation of its Medical Staff.—We are sorry to hear that there has been a serious disagreement be-tween the managers and the medical staff of the St. Michael's Hospital, at Newark, N. J. From what can be learned, it appears that the recommendations of the medical board concerning the filling of a vacancy in its membership were not only ignored by the trustees, but were actively opposed by the managers to the extent of appointing a gentleman whom the staff declined to nominate. The same principle of oppo-sition on the part of the trustees to the desire of the staff was manifested in declaring its election of a medi-cal director null and void, and in the appointment by the trustees of another gentleman to the position. While the former action of the managerial board might be mildly considered as discourteous, the lat-ter action was insulting, and the medical board very properly resigned in a body. If there is one privi-lege which should be enjoyed by the medical board of any hospital it is the one of choosing its associates. Its recommendations regarding the qualifications of any candidate should command due respect from the appointing power. At least the board of trustees should not presume to elect any one who has failed to obtain the recommendation of the medical board. The trustees, doubtless, have the power to do this, but it is not always in the true interests of the hos-pital to exercise such power.

Another Audiphone.—We have chronicled the failure, or partial failure, of the Rhodes' audiphone. Another instrument for assisting hearing, the Gray-don audiphone, has been constructed by an English-man, and it is claimed to have special advantages. It is in principle something like that of Mr. Rhodes; that is, it conducts the sound to the auditory nerve through the bones of the face. It utilizes the micro-phone, however, thereby intensifying sound. Let one take a common toy-telephone and hold the string, which is fastened to the centre of the dia-phragm, in the teeth. Then let another person talk into the telephone, and the essential principle on which the Graydon telephone is constructed will be understood.

NEW YORK CHARITIES.—About $5,000,000 are expended in charity and pauper relief of various kinds in New York city each year. Nearly one-half of this is raised by taxation, the rest being donated by charitable persons.

DEATHS FROM INHALATION OF ETHER.—Two cases of death from the inhalation of ether are reported in the *Boston Medical and Surgical Journal*. One was that of a man, in Providence, R. I., aged 54. He had been knocked down by a horse, and sustained injuries to the hip. Ether was given to facilitate the diagnosis. After taking it for about fifteen minutes, without any warning he ceased to breathe. The autopsy showed effusion of serum beneath the arachnoid, valvular lesions of the heart, and cystic degeneration of the kidneys.

The *Cornish Journal* reports the death of a lady from ether, administered by a physician for the purpose of extracting a tooth. Scarcely an ounce had been used. The coroner's verdict was death from paralysis of the heart, due to inhalation of ether.

ADULTERATIONS OF COD-LIVER OIL.—A Dutch paper is the authority for the statement that the cod-liver oil obtained from the torsk, which comes principally from Bergen, in Norway, is very often adulterated before exportation with the oil obtained from the livers of the Seymonus borealis (called in Norway "haakjärring"). This fish, which belongs to the shark species, abounds in the Polar Sea, in the northern parts of the North Sea, and in almost all the larger fiords on the west coast of Norway; it is caught at depths of one hundred to two hundred fathoms, and the larger specimens furnish from one and a half to two casks of liver. The oil obtained from it is beautifully clear, contains but little stearine, and is cheaper than the torsk oil, but it has a very unpleasant odor, and its taste is exceedingly disagreeable. Moreover, the fluid fat of the sea-mammalia (seals, etc.) is also sold as pure cod-liver oil; this oil contains but little fatty acid, and it is hard to digest. The adulteration with this last oil is said to be practised not in Bergen, but after exportation.—*Allg. med. Cent.-Zeit.*

UNIVERSITY OF EDINBURGH.—The medical school at this university has been greatly increasing in prosperity and in the number of its students, within the past five years. In reply to an insinuation that this was due in part to the laxity of its examinations, Dr. William Rutherford writes to the *British Medical Journal*, that in 1878, of 262 candidates at the first examination, 25.9 per cent. were rejected; of 165 at the second examination, 35.1 per cent. were rejected. At the final examination 144 appeared, and 18 per cent. were rejected.

Dr. Rutherford considers this a proof of the severity of the examinations.

There are some American colleges who reject a larger per cent. at the final examinations.

PRISON REFORM.—The doctor-governor of Kentucky has been doing good work in calling attention to the evils connected with Kentucky prisons. It appears that there are 953 prisoners and 780 cells, so that in many cases two have to sleep in a cell. This gives about 80 cubic feet of air to a person. This has seriously affected the health and working capacity of the men. *Louisville Med. News.*

HOSPITAL SATURDAY AND HOSPITAL SUNDAY.—The hospital Sunday collection in London recently amounted to over $130,000. One per cent. of this amount is devoted to the purchase of surgical instruments for poor patients. The plan of setting apart a portion for this object is highly commended by the *British Medical Journal*. Hospital Saturday in London meets with small favor, and but little money is raised on that day.

EXCISION OF THE HIP-JOINT.—At two successive meetings of the London Clinical Society, the operation of excision of the hip-joint was exclusively discussed. Mr. Croft championed it and showed a number of successful cases of his own. He insisted on the comparatively early performance of the operation and on the preservation of the great trochanter. A committee was appointed to investigate and report on the whole subject.

HUDSON RIVER STATE HOSPITAL FOR THE INSANE.—Dr. Allan McLane Hamilton, of this city, has been appointed one of the consulting board of this asylum.

CONTAGIOUS DISEASES IN CHARITABLE INSTITUTIONS.—There have been a number of epidemics of more or less extent in the charitable institutions for the care of children in this city. Over a month ago many cases of measles were reported from the Baby Shelter connected with the Church of the Holy Communion; since then that disease has appeared among the children in the Home for the Friendless, on East Thirtieth street. We learn that whooping-cough has prevailed extensively in the Mount Vernon branch of the Lying-in Asylum. The recent disclosures concerning the condition of the children in the Shepherd's Fold show that some of our infant and juvenile charities nurse disease as well as children.

CONTAGIOUS DISEASES IN NEW YORK.—According to the report of Sanitary Superintendent Dr. W. De F. Day, the number of cases of contagious diseases in this city in 1879 was as follows: typhus fever, 8; small-pox, 65; cerebro-spinal meningitis, 107; typhoid fever, 233; diphtheria, 1,781; measles, 2,424; scarlatina, 5,447.

The number of cases of measles, which was very great in December, amounting to 971, decreased somewhat in January of this year.

CLINICAL LECTURE ON GENERAL PARESIS:

BEING THE FOURTH OF A COURSE OF FOUR CLINICAL LECTURES UPON THE DIAGNOSIS OF INSANITY.

DELIVERED UNDER THE AUSPICES OF THE COMMISSIONERS OF CHARITIES AND CORRECTION, AT THE NEW YORK CITY ASYLUM FOR THE INSANE,

BY A. E. MACDONALD, M.D.,

MEDICAL SUPERINTENDENT, NEW YORK.

GENTLEMEN:—We are to consider to-day the fourth and last of the forms of insanity embraced in the classification which we agreed at our first meeting to accept, and it is not alone the last, but, to my thinking, the most important of those forms, and I have more than one reason for thinking so. In the first place, it is more recent, at least in its recognition, if not, indeed, in its origin, than the forms which we have discussed. Our knowledge of its course and causes and symptoms is much more limited and much less positive, and there is the further reason, which may increase the importance of the present opportunity of study to many of you, that, though prevalent enough in this neighborhood, it is comparatively unknown in those localities to which you may propose, after the completion of your studies, to remove.

I speak of paresis as a comparatively newly discovered form of insanity, and you will remember that we found its name to be a comparatively recent addition to the three forms of insanity of which Pinel's "natural system" of classification was originally composed. Now that the disease is recognized, and that opportunities for its study are ample, we see that its symptoms were observed and recorded long since; but so rarely were they observed that they were not held to constitute an individual form, but were simply regarded as accidental complications of one or other, indifferently, of the forms already recognized. Indeed, the date of its promotion abroad to the dignity of a distinct disease is within the present century, while in this country but little over thirty years have elapsed since its first appearance or identification; and although, since that time, the number of cases presenting its characteristics has in this neighborhood greatly increased, its extension toward the interior has been gradual, and there are still many localities, especially in the west and south, where it has not yet appeared. That it will do so the history of the disease and its geographical progress can leave no doubt, and hence my belief that it is especially important that you should study it here where it is common, in order that you may recognize it if you go where it is now unknown, but will surely follow.

I speak to you of the disease by the name commonly applied to it in this country—"General Paresis." English writers, as a rule, use the longer term —"General Paralysis of the Insane"—while individual authors have each their own designation, "Paralytic Dementia," "General Incomplete Paralysis," "Progressive Paralysis," among the number.

The use of the word "progressive" in one of these designations is a happy one, for progression is a principal characteristic of the disease, exaltation being another. In effect, general paresis may be defined to be a form of insanity in which there is an association of mental and physical evidences of which progression and exaltation are the leading characteristics. As the patients in the different stages of the disease are presented to you, you will observe how constant and uniform these characteristics are. You will see, first, that they are—at least those in whom the disease is of relatively recent development—men of apparently strong frame and vigorous health. Paresis does not find its victims, as do commonly the other forms of insanity, among those who are weakened by constitutional defect or by disease, but selects them from among the active and vigorous. Nor does it go to the extremes of age, but to the prime of manhood.

I will anticipate the appearance of the patients by giving you a brief summary of the leading symptoms of the disease and of its course, and as the patients are brought before you, you will recognize these symptoms and others which are less uniform in their presence.

As a rule, then, paresis makes its appearance in a man of middle age who has apparently been possessed of a strong constitution and of robust health. It is quite possible—probable, indeed—that he has been somewhat inclined to dissipation or excess in various ways; but it has not gone to the point of perceptibly affecting his health, or appearance, or business capacity. The change which comes over him is rather a more sudden one than in most forms of insanity excepting acute mania, and it is somewhat of a question whether the mental or the physical symptoms have precedence. Generally, in the statements of friends, the first place is assigned to the former, but they are plainer and more likely to attract the attention of the laity; and it is probable that if all cases could be carefully observed and the two sets of symptoms appreciated, they would be found to appear and advance coincidently. As regards the mental evidences, as in the approach of other forms of insanity, a period of irritability and depression may be expected; but it may be but slight and transient, and attract no attention. Then the element of exaltation asserts itself; the patient is lively and excited; he feels well in body, happy in spirits, hopeful and confident in business. He is disposed to enjoy life, to eat, drink, and be merry, and to make his companions and acquaintances share in his enjoyments. He becomes speculative and reckless in his transactions, extravagant and wasteful in his expenditures and his bounties; and before his condition is fully recognized and his property protected, he is apt to hopelessly embarrass his affairs. Increase in these tendencies, loudness in speech and manner, eccentric dress, indecency of language and demeanor, and possibly acts of violence, pave the way for positive delusions, and, as I have said, the main feature of these is their exaltation or exaggeration. In whatever field the patient's fancies may wander, they carry him far above his fellows. He is the richest, or the most powerful, or the most learned; or if, as sometimes happens, a melancholy tinge is imparted to his thoughts, he is the most abused and the most wretched.

All this time the physical symptoms have been appearing and progressing, depending upon increasing loss of power of co-ordination in the voluntary muscles. The muscles of the tongue and lips, as those most delicate in their functions, are the first to suffer or to show it, and there are, as a consequence, alterations of speech. At first it is but a slight hesitancy or catching, but it becomes thicker and more drawling, and the enunciation is indistinct and halting,

despite the patient's manifest efforts to speak with distinctness and deliberation. At the same time the muscles of the lips are tremulous, and the patient has difficulty in protruding the tongue, and while it is out it quivers and jerks, and may be suddenly withdrawn without deviation. There is evident failure, too, in the co-ordinating power of the muscles of the extremities; but these, as well as characteristic alterations in the conditions of the pupil, can be better shown to you from the patients themselves.

From this beginning the patient goes on surely, but more or less rapidly, through increasing exaggeration of delusions mentally and increasing paralysis physically, to the end. I may say now, before the patients come, that they may not hear me, that this end is death. The list of therapeutic agents has been ransacked, the pathological appearances studied, but as yet to no useful purpose. It is true that recoveries have been recorded, but they are at best insignificant in number, as well as doubtful in authenticity. Nor is the inevitable end long of being reached when once the disease is fully established. Three years is a long limit for most cases, though some have passed it. The longest period elapsing between development and death, in a case coming under my own care, has been short of six years. In these cases death occurs from the disease uncomplicated, and may either result from the gradual increase of the paralysis and its extension to the muscles concerned in deglutition and respiration, or from the convulsive seizures which come on in its course. In other instances, pulmonary complications arise and end the patient's life.

Phthisis is a not uncommon complication of general paresis, as indeed of other forms of insanity, and when it is present it seems to have an effect in shaping and coloring the delusions. It is in such cases that you will find the tendency toward depression that I have spoken of as occasionally existing. It stops short of the depression of true melancholia, however, and only modifies without supplanting the delusions of greatness or wealth. The patient may tell you that, through the machinations of his enemies, he has lost his kingdom or his fortune; but he will tell you, too, that his loss is but a temporary one, and that he will soon be more powerful or wealthier than before, and as, at any time, the ravages of the pulmonary disease may be temporarily arrested, the original delusions will return.

Case I.—The patient whom I first present to you will show excellently the physical marks of the disease. In his case the progress of the malady has been rapid, but seven months having elapsed since its appearance. He is thirty-two years of age, and has evidently been a man of fine physique. You do not get many mental symptoms from him, for he has already passed from the lively and talkative into the dull and stupid stage; and, besides, his speech is so stammering and incoherent that his answers to our questions are scarcely intelligible. You see very plainly here the tremulousness of the lips and tongue of which I spoke. He can only protrude the latter with the greatest difficulty, and has little or no control over it. His hands and limbs are equally independent of his will; the former tremble and jerk about, and his gait is so unsteady and tottering that he seems in constant danger of falling.

You notice that there is a decided inequality of his pupils, the left being much dilated and failing to respond to light, while the right is about normal in size, and does so respond. This is a lesion which is almost characteristic of general paresis, and which, when associated with the mental evidences of which we have spoken, may be taken as settling the question of diagnosis. It is true that unequal pupils may be found in other cases, and even in sane people; but in the latter a history of mechanical injury, or of strain by excessive use of one eye, as in the case of engravers, may generally be found to account for it. In the case of paresis, at the inception of the disease, there is usually intense and equal contraction of the pupils—"pin hole" pupils, as we call them—but subsequently they dilate, and dilate unequally. They are apt to lose their shape, too, and become irregular, from lapping over of the edge of the iris. In some cases the right pupil is the more dilated, in others the left, and a curious fact in this connection, first recorded by Dr. Austin, in England, and verified by observations in this asylum, deserves to be mentioned. This is that where there is any tendency toward melancholy or depression, the left pupil will be found to be the larger, while where the opposite tendency exists, as it does in the great majority of cases, the right pupil will be the more dilated. I do not venture to account for this relation, but it certainly seems to exist, as you will see, I think, from the patients before you.

I may speak to you now, as well as at another time, of the probable causes of paresis. Of the general type of persons from which its victims are selected we have already spoken, and it will prepare you for what follows. The assigned cause in the case of the patient before you is excessive sexual indulgence, and in my experience it is the assigned or assignable cause in the great majority of cases. There is the source of error to be feared in this case which affects all attempts to ascribe causes to attacks of insanity of any kind—the doubt as to the real relations of cause and effect. Hence, if we get concerning a paretic the history of excessive venery, we may, especially if the history is only of recent indulgence, suspect that the excess is due to the disease and not the disease to the excess, and we may admit at once that we do have cases of paresis where there is not only no reason to suspect over-indulgence, but where the negative evidence is so conclusive that we have to seek for other causes. But in the great majority of cases, at least of those coming to this asylum, there is a straight history of inordinate venery, and strong corroborative evidences and appearances. With this we get too, in most cases, a history of hereditary tendency to insanity, and of intemperance in the use of stimulants; but this is true, too, of the admissions generally, and not alone of those suffering from paresis. Other assigned causes are sunstroke, syphilis, and injuries to the head; but, as compared with the cause I have cited, they are infrequently advanced, and this leads me to say a word regarding the question of sex in the matter of liability to this special form of insanity. It is an undoubted fact that excessive sexual indulgence is less disastrous in its effect upon the female than upon the male, and, therefore, if it is really the principal factor in the production of paresis, we should find that disease much more prevalent among men than women, and this is exactly what we do find. In this asylum, which, as you know, receives males exclusively, there are now probably a hundred cases of paresis. In the corresponding asylum of the department devoted to the care of females, although the entire number of patients is much greater than here, there are, according to the report of the Superintendent, not more than three or four; and, by way of further confirming the theory advanced, it is recorded that, where women suffer from

paresis, they are generally those who have led dissolute lives as professional prostitutes.

It is noticeable that, when paresis first makes its appearance in a given locality, its victims are exclusively males. As time passes on, a few cases are found among females, and thereafter their proportion increases as the disease spreads.

Case II.—This is also a comparatively recent case of paresis, the invasion of the disease dating back only five months. He is a younger man than the other, about twenty-seven, and you see that the physical disturbances are by no means so far advanced. In fact, at first glance, as he sits there, he appears a well nourished, healthy young man. But as he rises and comes toward us we see that his gait is perceptibly affected, that his hand is tremulous, and that his pupils are unequal, the right being this time the larger. When he speaks, the difficulty of articulation is marked; but we can understand him distinctly enough, and learn the drift of his delusions. They are, as is commonly the case, at least in the commencement of the disease, connected with his former pursuits in life; they are limited in number, and are by no means as exaggerated as those shown by some, or as they are themselves likely to become as the disease advances. He was, prior to his admission, a professional billiard-player, a champion in one branch of the game, and but recently engaged in a tournament in this city. Accordingly he accounts for his residence here by telling us that this is a large hotel, that he has charge of the billiard-room, with a fabulous number of tables, from which he derives a large income, and that the only feature of the establishment to which he objects is the fact that the door of the bar-room is always kept locked, and that he cannot get access to it. As it happens, there is another patient in his ward, a paretic also, who was likewise a billiard champion, or thinks he was, and these two worthies spend much of their time in discussing the preliminaries of a grand championship match which is to settle the question of supremacy between them. It is needless to say that the stakes are something enormous, and that each is sublimely confident of his ability to win them.

Now here are two patients, the delusions of each of whom depend largely upon belief in the entire truth of the delusions held and enunciated by the other. This is a peculiarity which you often find among patients with paresis, and do not find among patients with other forms of insanity. You will remember that at our former meetings, and especially when we had the maniacal patients before us, there were often implied, and sometimes audible, expressions of dissent on the part of other patients from the views of the particular patient who happened to be addressing you, and these views were often ridiculed and laughed at. As a rule, an insane man appreciates the falsity of the beliefs of other insane men around him, while cherishing beliefs equally false himself. And this is a fortunate thing for the officers of asylums, for it prevents the association of patients in schemes for attack or escape. Should one patient invite the co-operation of others in a plan to escape, the chances are that they would inform upon him, believing him quite unfit to be at large, while each considering for himself that his own detention is quite unwarrantable; and where a patient attacks an officer, it is quite common for other patients to interfere for his protection. There is, then, usually but little confidence between the insane, and but little acceptance of the delusive ideas of one by the other. But the paretics are in some measure an exception to this rule. It is by no means uncommon for one of them to uphold the correctness of the assertion of his fellow-patient almost as loudly as his own, unless, indeed, those views clash with his, in which case, of course, the other man is all wrong, just as in the case of sane people.

This patient, and the other of whom I have spoken, hold each the delusion that he is going to win money from the other, because he believes the delusion of the other that he has got money to lose. Similarly, a patient who was formerly a professional gambler plays cards with his comrades industriously, cheats incorrigibly, and flatters himself that he is rapidly absorbing the millions they claim to possess; and in more legitimate business there are transactions made and copartnerships formed that are quite dazzling in their results, and always equally productive to both parties.

Case III.—This is an exceptional patient in one or two respects. In the first place, he is much beyond the usual age of paretics, being aged 66; and in the second place, the disease has lasted an unusually long time to have reached only its present stage, for he has been an inmate here for five years. You see that he is a lively little old gentleman, fat and good-natured, very talkative, and with a disposition to assume the direction of affairs and generally assert himself. There is surprisingly little physical disturbance for one in whom the disease has endured so long, and whom it has at times affected so hardly—for he has more than once been at the point of death from the epileptiform attacks which are incident to paresis. The affection of the speech and gait, though perceptible, are not marked, and the difference in his pupils is the only decided physical symptom present. The right pupil is again in his case the more dilated, and he feels that there is some trouble with his vision, and is constantly asking for spectacles, which, of course, fail to correct it. But, if the physical symptoms are absent—or in abeyance, for he has shown them decidedly enough at other times—there is no lack of the mental ones. His delusions cover every conceivable subject, and reach quite inconceivable heights. There is no difficulty in eliciting them either, for he is very garrulous, and always glad to have an opportunity for speech-making. He has been brought before classes so often now that he is quite prepared for it. Often, as I pass through his ward, he asks when he is to have an opportunity of delivering himself; and he is constantly preparing discourses upon the most diverse and abstract topics. In all the insane, the delusions, as we have seen, relate to themselves, and first to the condition of their own bodies and minds. You will remember this in the maniacal and melancholic classes, and you will discover it in this patient and in his class. He tells you that he is the strongest man in the world, that he has defeated all the noted pugilists, none of whom could strike him a blow; and he offers you an opportunity, which we will waive, of seeing how easily he can defeat myself. His health, he tells us, is "first-rate," and it is a singular thing how commonly paretics will answer the same inquiry with the same expression. Sankey, an English alienist, first called attention to this curious little point; I have often, in trying it, got the answer "first-rate" from eight or nine out of ten patients addressed, and I think you will be able to verify the result if you try the experiment for yourselves when we come to pass through the wards. This feeling of well-being and health marks the paretic to the end, and his contentment and happi-

ness render his disease the least trying, although the most fatal of the forms of insanity. Up to the last moment, when the patient cannot rise in bed or move a limb, or swallow, he will tell you that he is first rate, that his remaining in bed is only a matter of choice, and that he could rise and take part in the most active pursuits, if he so willed it.

In the patient before you the delusions by no means limit themselves to his strength and prowess. He is of great beauty and strength, to be sure, and has lived for millions of years, and made millions of money, part of which is invested in the building in which we are now visiting him. But it is rather upon his intellectual and artistic abilities and achievements that he prides himself. Apart from painting the works that have been erroneously ascribed to Raphael, and with the exception of the Bible, which he wrote to oblige his friend Martin Luther, the most satisfactory outcome of his genius has been a series of plays which he published under the *nom de plume* of "Shakespeare." He tells you this with all earnestness and gravity, and proceeds to quote from his works, commencing rightly enough, but soon wandering off into disconnected nonsense. It does not do to accuse him of this, however for he demands, with great promptness and some asperity, whether, having written the work in the first place, he is not privileged to alter it as he may see fit? He is a linguist too, as well as a litterateur, and boasts a thorough acquaintance with all the known, and several of the unknown tongues. To Germans or Poles among the patients, he will occasionally address himself, using the most absurd gibberish, and complacently attributing their inability to understand him to their ignorance of their own language. He has matrimonial aspirations too: offers himself and tempting settlements to any lady who visits the ward, and justifies himself to us by asserting that his first wife—Queen Victoria—is undoubtedly dead, she having been stolen from him by the Pope some centuries since. For the rest, he is now the contented, self-satisfied man that you see, though at one time he was noisy and destructive and filthy. He imagines that he leaves the asylum whenever he wants to, and gives circumstantial accounts of his excursions and adventures. His imagination transforms the asylum dinner into one of many courses and ample accompaniments, and there is nothing to mar his happiness. He has the usual history of excessive venery, as, indeed, had the patient who preceded him.

Case IV.—This is the last patient that I shall introduce to you here, for I think that it will be more to your profit to spend the time remaining in the wards, in closer examination of individual cases. I present him only that I may have a text for briefly calling your attention to a couple of points, in relation to the disease, which the other patients did not specially call out. In the first place, this man comes to us, not simply as a patient committed for treatment and care, but as a prisoner under indictment. The crime charged against him is forgery, and it was not until his trial was in progress that suspicion of his insanity was suggested, and he was sent here for examination and report. He is a paretic, evidently, and his forgery, which was of a note or check, was, no doubt, committed under the influence of delusions as to his wealth, which he now manifests plainly enough. Many of our paretic patients come to us after arrest and appearance before the courts, and some after sentence even. The evidences of paresis, as you have seen, are not greatly unlike those of drunkenness, and they sometimes lead to mistaken diagnosis upon the part of the finest police force, and even to misdirected therapeusis in the matter of clubs.

Where graver crimes have been alleged against them, they have usually been those of arson or of false pretences. The paretic is very apt to set fire to his residence with the view of replacing it by one better suited to his newly acquired wealth and position; or he may obtain goods upon false representations as to his solvency and ability to pay for them.

You will observe that this patient does not give a very definite summary of his wealth; he indicates its extent rather by comparisons than by dollars and cents. This use of the comparative is a common thing among paretics when they are speaking of their powers, or attainments, or possessions. They are richer than Rothschild, or "bigger men than old Grant," and they are very apt to spell it with one "g," too, for the evidences of their disease find their way into their letters very speedily. Apart from the alterations in the handwriting consequent upon the loss of co-ordinating power, there are lapses in spelling and grammatical construction, even on the part of those who were before the most accurate. This, of course, comes from the lapse of memory, upon which the delusions also largely depend.

Original Communications.

BORACIC ACID—A NEW REMEDY IN EYE DISEASES.

By SAMUEL THEOBALD, M.D.,

SURGEON TO THE BALTIMORE CHARITY EYE AND EAR DISPENSARY; OPHTHALMIC AND AURAL SURGEON TO ST. VINCENT'S HOSPITAL, BALTIMORE.

It is with much pleasure I hasten to bring to the notice of the medical profession, and more especially to the attention of those engaged in ophthalmic practice, the astonishingly favorable results which I have recently obtained in the treatment of certain affections of the eyes, from the use of boracic acid, an agent which, so far as I am aware, has not been heretofore employed in ophthalmic diseases.

Boracic acid, which, until Lister brought it into notice as an antiseptic, was little used except in the manufacture of biborate of soda, is a mild astringent. A solution containing four grains of the acid to an ounce of water—which faintly reddens litmus-paper—when shaken in a test-tube with an equal quantity of the white of an egg, produces but a slight coagulation of the albumen; and even a saturated solution* acts much less energetically in this respect than does a one-grain solution of sulphate of zinc. Its antiseptic properties, according to Lister, are not so great as those of carbolic acid; nevertheless he recommends it in certain cases, because of its being less stimulating to the tissues.

In an article upon the "Antiseptic Treatment of Suppuration of the Middle Ear," published in the *Archiv fur Ohrenheilkunde*, Vol. XV., Part I., Bezold described the excellent results which he had obtained in this affection from finely powdered boracic acid, applied by insufflation to the external auditory meatus. An abstract of this paper, which appeared in the October number of the *American Journal of Otol-*

* At 72° F. an ounce of distilled water will dissolve twenty grains of the acid; in hot water it is more freely soluble.

ogy, came to my notice some weeks since, and induced me to experiment with the new remedy. The results which I obtained in a number of cases of otorrhœa were not less favorable than those which Bezold had reported; they led me, however, in one respect to a different conclusion. He placed but a poor estimate upon the efficacy of *solutions* of the acid, deeming it as essential that it should be used in *substance;* whereas, I obtained, in some cases at least, such very excellent results from solutions, varying in strength from five to ten grains to an ounce, as to induce me to place a higher estimate upon their value.

The prompt manner in which purulent discharges from the mucous membrane of the tympanal cavity were checked by these solutions, suggested the idea, that where similar discharges from the conjunctiva existed, equally good results might be obtained from their use as a collyrium. The first point to be ascertained, whether the eye would be unduly irritated by the application of the acid, was soon settled, and in a most satisfactory manner—*a four-grain solution when dropped into the eye was found to cause absolutely no irritation.* Even where a half-grain solution of sulphate of zinc gave rise to considerable smarting, the boracic acid induced not the slightest discomfort. A case of purulent ophthalmia, under my care at the Baltimore Charity Eye and Ear Dispensary, afforded an excellent opportunity for further experimentation. When this case came under observation—the disease having been allowed for three weeks to run its course unchecked—a threatening corneal ulcer was present in each eye, while the purulent discharge was still as great as ever. Fearing, because of the condition of the cornea, to use a stronger astringent solution, I had at first given a collyrium, to be applied four times a day, containing half a grain of nitrate of silver and one grain of atropia to an ounce of distilled water, which was well borne, but produced only slight diminution in the discharge. The proportion of nitrate of silver, therefore, was doubled; but in this strength, though it further checked the discharge, it caused so much irritation that I could use it but twice a day, alternating it with a one-grain solution of atropia.

Under this treatment the disease was slowly subsiding, the ulcers becoming less threatening, and the discharge less profuse; nevertheless at each visit I found it necessary to remove a great quantity of purulent secretion from the eyes, in order to obtain a view of the cornea, and the palpebral conjunctiva was still swollen and villous.

It was at this stage, after three weeks' use of the nitrate of silver, that the boracic acid was employed. Giving a solution containing four grains of the acid and one of atropia to an ounce of distilled water, I directed it to be dropped into the left eye (in which the ulcer was more completely healed, though the discharge was not less profuse, than in the other) three times a day, in place of the nitrate of silver and atropia, which, however, were to be used as before to the right eye. This was on Monday. The case was next seen on Wednesday, when, in response to my question as to how the eyes were getting on, the reply was: "One eye is a great deal better." And so it certainly was. To my great satisfaction the left eye was found to be entirely free from discharge; not a particle of pus, or even of mucus, could be discovered within the palpebral aperture, while the corneal ulcer was healing nicely, and the conjunctival swelling had greatly diminished. The other eye had changed but little, and still contained as much pus as before. The same treatment was now ordered for it. During the next two days, however, the patient—a wretched little specimen of illegitimacy, but half-nourished because of the illness of its mother—took a bad cold, which came near putting an end to its existence. The consequence was, that on the following Friday, although there was a decided diminution in the discharge from the right eye, the left was not so well, and contained a small amount of muco-purulent secretion. Nevertheless, in spite of this drawback, and an attack of thrush which next supervened as a consequence of improper feeding, the inflammation of the eyes rapidly declined under the influence of the acid, which caused not the slightest irritation; so that in three or four days the swelling of the lids and conjunctiva had entirely disappeared. At the expiration of a week, as a slight blennorrhœa still persisted, and the ulcers had so far healed as to give rise to no further anxiety, I ventured to increase the proportion of boracic acid in the collyrium, which was still being used three times a day, to eight grains to an ounce. This caused no irritation, but as a slight mucous secretion persisted after several days, it occurred to me to discontinue the atropia, which up to this time had been combined with the acid. The change was immediately beneficial, and in twenty-four hours the secretion had nearly ceased. The case is still under observation, the drops as yet being used; but the subject of it, barring his eyes, is in so wretched a condition that I fear he will not live to enjoy the excellent vision which has been saved to him. Should, however, his fate be an early demise, he will, hereafter, doubtless derive additional enjoyment from a conciousness that his mundane existence, though brief, was not altogether in vain.

The next case in which I tried it was that of a boy, thirteen years old, the subject of inherited syphilis, who, while under treatment for an obstinate and severe sclero-keratitis of specific character, was attacked with a catarrhal conjunctivitis. After having satisfied myself that this was not produced by the atropia which was being used, I had tried in succession mild solutions of sulphate of zinc, alum, and nitrate of silver, but each with no appreciable benefit. The conjunctival inflammation seemed to be rendered peculiarly obstinate because of its association with the more serious corneal and sclerotic affection, so that, in spite of the various astringents which were employed, the catarrhal condition persisted, and I invariably found upon eversion of the lower lid an accumulation of mucus in the retro-tarsal fold.

After this treatment had been persevered in without effect for six weeks, a two-grain solution of boracic acid was given, to be dropped into the eyes three times a day. It caused no irritation whatever, and when, after two days' use of it, the eyes were examined, the catarrhal inflammation had disappeared, and I sought in vain for the usual accumulation of mucus. Although it is now being used but twice a day (the case being still under observation), there has been no return of the conjunctivitis; but, on the contrary, so rapid and decided an improvement in the sclero-corneal inflammation, which before had changed but little from week to week, as to convince me that upon this also it has exerted a decidedly beneficial influence.

After this I began with more confidence to make use of the new remedy. Even a saturated solution, when dropped into the eye, I found, although it gave rise to a constringent sensation analogous to that which alum produces in the mouth when tasted, caused only a very slight momentary smarting, accompanied by a trifling injection of the conjunctival vessels, which

disappeared in two or three minutes. The two- and four-grain solutions had only occasioned no irritation, but when an irritant is previously existed, produced a decidedly grateful sensation, which was described as soothing and cooling.

Among other cases in which I have since used it, the following may be briefly mentioned as illustrating its action, and as indicating the different conditions to which it seems applicable:

A patient, one of whose eyes I had enucleated four weeks previously, was much annoyed by an excessive secretion of mucus from the conjunctival sac as soon as he began to wear an artificial eye, and this in spite of his having used for some time before a four-grain solution of alum. A solution of boracic acid of the same strength was ordered to be instilled two or three times a day. He used it only twice a day, but in twenty-four hours the discharge was greatly diminished, and in two days was so far checked as to give him no further inconvenience.

In two cases of myopia, complicated by astigmatism, in which, in spite of the use of correcting glasses, asthenopia persisted, accompanied occasionally by conjunctival hyperæmia, the acid is now being used with decided benefit: in one a four-grain, in the other a two-grain, solution, in order to compare their action. In each a one-grain solution of sulphate of zinc had previously been tried, and abandoned because of the irritation which it produced; while in one alum, acetate of zinc, biborate of soda, and acetate of lead, had likewise been used without benefit. The case in which the four-grain solution is being used is that of a young lady, seventeen years of age, who, as she is completing her last year at school, and is a hard student, has exacted of her eyes during the past three months an undue amount of day and night work, and, as a consequence, has suffered much with asthenopia attended by congestion of the lids and conjunctiva. Since using the acid, her eyes have looked and felt much better, and she expresses herself as greatly pleased with its action.

An acute conjunctivitis of catarrhal type, attended by an unusual amount of irritation, in a lady about forty years of age, in which a one-grain solution of sulphate of zinc had done more harm than good, yielded at once to a two-grain solution of boracic acid, each application of which lessened the irritability of the eyes, instead of increasing it, as the zinc had done. In a number of other cases of acute catarrhal conjunctivitis, I have obtained from it equally good results, while in a chronic conjunctivitis, associated with nasal catarrh, it is being used with decided benefit.

In a case of kerato-conjunctivitis of scrofulous character in a little girl, attended by great photophobia and lachrymation, which did not yield to atropia and yellow oxide of mercury, I ventured to apply a two-grain solution of the acid, and finding it produced no smarting or irritation, I added one grain of atropia to it, and directed it to be used three times a day. It was well received, and decidedly lessened the conjunctival inflammation; but, on the fourth day, as the photophobia seemed rather greater, I gave in its stead a four-grain solution of atropia. After two days' use of this, the photophobia was somewhat lessened, but the conjunctival injection increased. A two-grain solution of the acid was then given, to be applied thrice daily, and to be followed by the atropia. In two days the redness had again disappeared, and in four days more the photophobia had gone, and the eye was free from inflammation.

In another case of scrofulous kerato-conjunctivitis, with a large pelvet-cula upon the cornea, a solution of the same strength was used in connection with atropia for two days, without causing any irritation whatever, when, as the improvement was not satisfactory, yellow oxide of mercury ointment was substituted with advantage.

These two cases are of especial interest as showing how entirely free from irritating properties the acid is, for there is perhaps no condition in which the eye is so intolerant of a stimulant as in scrofulous keratitis, and had I used in either of these even a quarter-grain solution of nitrate of silver, or a half grain solution of sulphate of zinc, the consequence would in all probability have been decidedly unpleasant.

In a patient of strumous diathesis, under treatment for stricture of the nasal duct, a superficial keratitis of the affected eye, accompanied by conjunctival injection, supervened, and proved of most obstinate character. Besides constitutional remedies, atropine, pilocarpine, belladonna and opium fomentations, and hot water, had each been tried in vain. Finally, an ointment of iodoform (gr. x. to vaseline, ʒj) was tried, and under its influence and that of atropia a decided improvement set in; when suddenly, and probably as a result of the long-continued use of the atropia, a catarrhal conjunctivitis appeared. Fortunately, I had by this time learned the virtue of boracic acid, and so, discontinuing the other remedies, I ordered a two-grain solution of it, to be applied three times a day. In three days the conjunctivitis disappeared, and when I next saw my patient, at the end of a week, no redness remained, and the cornea was better than it had been for weeks.

A girl, seventeen years old, with extensive nebulous opacities in the cornea of the right eye, the remains of a severe scrofulous ophthalmia, reported at the dispensary a few days since, suffering from a recurrence of corneal and conjunctival inflammation. She had previously had several such relapses, and they had usually yielded, though slowly, to atropia and yellow oxide of mercury. In this instance I directed simply a two-grain solution of the acid to be applied three times a day, first, however, instilling a ten-grain solution, which produced no more smarting than as much water would have done. In two days she returned, with the inflammation entirely relieved.

How far the good effects of the boracic acid in the cases I have related were due to its antiseptic properties, and how far simply to its astringent action, I am not prepared to say, though I am disposed, since it is so feeble an astringent, to ascribe them, and more especially its influence over purulent and catarrhal conjunctivitis, in great part to the former. However this may be, I am confident that in the treatment of eye diseases, boracic acid has open to it a wide field of usefulness; and unless the results which I have obtained from it thus far prove to be exceptional, I believe it will, ere long, obtain a position in ophthalmic therapeutics second only to that of atropia. To those who are sufficiently familiar with this department of surgery to appreciate the immense advantage which will accrue from the possession of an agent capable of arresting purulent and muco-purulent discharges from the conjunctiva, and yet so bland in its action as to cause no irritation, even in phlyctenular keratitis, this prediction will not seem unreasonable.

The affections to which it seems especially adapted are: purulent conjunctivitis, including gonorrheal ophthalmia, and ophthalmia neonatorum; catarrhal conjunctivitis; asthenopia from whatever cause aris-

ing, and the conjunctival hyperæmia which usually accompanies it; and, I think I may add, granular conjunctivitis, although it so happens that I have not yet had an opportunity of testing it in this condition. In phlyctenular ophthalmia, atropia and yellow oxide of mercury in most cases leave little else to be desired, but when the inflammation is chiefly conjunctival and somewhat catarrhal in type, these remedies do not always act so well, and in this condition boracic acid will, I think, be found of service. In relieving atropinism, and when used with the atropia in preventing it, it is undoubtedly efficacious. In inflammatory affections of the cornea my experience of its action is as yet limited, but so far as it goes is *decidedly* favorable; and I would recommend its use in pannus, in ulcerative and suppurative keratitis, and in the various forms of diffuse corneal inflammation. As an adjunct to the probe in the treatment of lachrymal affections, it promises to be of much value. In marginal blepharitis, an ointment, containing ten grains of the acid to a drachm of simple cerate, has been of unmistakable service in some cases. And, finally, with boracic acid substituted for carbolic acid, the principles of antiseptic surgery may be applied to the graver operations upon the eye, with a prospect of better success than attended the recent experiments of Alfred Graefe in this direction.

As to the proper manner of employing the acid in the different conditions I have enumerated, much will have been gathered from what has gone before. In asthenopia, in catarrhal conjunctivitis, and in keratitis, I would recommend a solution containing from two to four grains to an ounce of distilled water, giving preference in most cases to the latter strength. As a rule, three or four times a day will be sufficiently often to apply it, but, if necessary, I believe it may be used more frequently with safety. In the different forms of purulent conjunctivitis, and more especially in gonorrhœal ophthalmia, stronger solutions will probably be required; and since even a saturated solution (gr. xx. to ℥ j.), as I have before stated, causes only the most trivial and momentary irritation, I think it will be better, when the case can be kept under observation, not to trust to one of less strength.

It would be deemed, perhaps, an oversight, should I conclude this paper without alluding to the fact that for a long time biborate of soda has enjoyed an extensive reputation in eye diseases. It so happens that my experience with this salt has not been such as to induce me to place much confidence in its efficacy, and so I have seldom employed it, and, it may be, have underestimated its value. Such virtue as it possesses, I am now sure is derived from the boracic acid which enters into its composition, and which, through its union with soda, seems to lose in great part its efficiency.

Since the foregoing was written, I have had an opportunity of testing the acid in a second case of ophthalmia neonatorum, in two cases of chronic granular conjunctivitis with pannus, and in three cases of corneal inflammation of traumatic origin. In the first named, where there existed a profuse purulent discharge, a ten-grain solution was ordered to be dropped into each eye every three hours. In twenty-four hours there was an appreciable diminution in the discharge; in forty-eight it was greatly lessened, and had lost its purulent character; and to-day (this being the fourth since the treatment was commenced) the discharge is slight, the swelling of the lids and conjunctiva nearly gone, and the eyes are already out of danger. The child was six weeks old; the inflammation had begun about the ninth day, and had grown much worse during the few days preceding the inception of the treatment.

In the next two cases, I began with a four-grain solution. In one this is still being used with decided benefit, in the other, in which an acute attack of corneal and conjunctival inflammation had set in, it had no effect, but a twenty-grain solution which has been instilled thrice daily for the past three days has been well received, and is certainly doing good.

In the last three, the effect of a four-grain solution has in each been surprisingly favorable. One of them, a stone cutter, while suffering from a catarrhal conjunctivitis, received a blow from a bit of stone upon the right cornea. After having used atropia for several days, his eye meantime getting worse, he came to me with a decided conjunctivitis, the lower half of the cornea quite misty, and a more opaque spot, with epithelium abraded, just below the centre of the cornea, marking the site of the wound. The atropia was discontinued and boracic acid only used. It produced a much pleasanter impression upon the eye than the atropia had done, and in two days the mistiness of the cornea and the conjunctivitis had disappeared.

It is evident that besides the astringent and antiseptic properties which boracic acid possesses, it exerts, when applied to the eye, a topical influence which may be properly termed sedative or anodyne.

6 Cathedral St., Baltimore, Jan. 16, 1880.

THE HEATONIAN OPERATION FOR THE CURE OF HERNIA.

By W. B. DeGarmo, M.D.,

New York.

In 1871 I became interested in this method of curing the three forms of abdominal hernia designated inguinal, femoral, and umbilical.

As I was then devoting my entire time to the study and mechanical treatment of these affections, I was frequently brought into communication with cases which had been operated upon by Dr. Heaton, in most instances successfully, and by all it was endorsed and spoken of as a simple, almost painless operation. Being desirous of becoming familiar with the procedure, I addressed a letter to Dr. Heaton in April, 1872, asking if he would inform me as to his method of operating. In response he told me, in a very gentlemanly manner, that he had not seen fit to give to the profession the operation he had been successfully using for the preceding twenty or more years; but, as he contemplated at some future date making it known, that I, with others, would have all particulars concerning it. During the next five or six years I met with others who had been under his treatment. From the early and increasing interest which I had taken in this operation, it was with great pleasure that I received one of the first copies of Dr. Heaton's work, sent to this city in 1877.

After its careful study I became even more firm in my conviction that there was merit in it, and, in conversation with Dr. Geo. F. Shrady, so expressed myself; and I then entertained the hope that those surgeons whose hospital appointments gave them ample opportunity, would test it and place the operation upon its true basis. In the latter I have, however, been disappointed, as it has been given very little attention by the profession, with the exception of Dr.

Shrady, who has from the first looked upon it with favor. This fact may be attributed to two causes, viz. 1st. That Dr. Heaton, from keeping his method secret, was ostracized from the regular profession, and justly looked upon with distrust. 2d. That the simplicity of the procedure created a lack of faith in the minds of surgeons who had always hitherto been taught to look upon hernia as incurable, except by operations of greater magnitude. The question now is: Are these sufficient causes to warrant the profession in casting this operation aside without consideration or trial? I think not.

Dr. Heaton, in his earlier days, invited certain then eminent men in Boston to be present at one of his operations. I am reliably informed that it was the manner in which they treated this invitation which first induced him to keep from the profession that which he had expected to give them. Shortly after this he went to England, where he operated in the presence of some of the most noted surgeons of that day. Sir William Fergusson, who witnessed the operation and its results, without being informed as to how it was done, says of it:

"From circumstances which have come to my knowledge, I think it possible that something more than is yet generally known may be done for persons afflicted with hernia. Some years ago I saw in London a gentleman of high standing and character in the United States, who had been radically cured of a reducible crural hernia. I afterward saw the surgeon who professed to practise this method, and was promised the knowledge of it provided I permitted reference to my name and bound myself to secrecy. I declined such a compact, but offered every other facility which either King's College Hospital or my own position could command. These proposals were not complied with; and I should scarcely have considered myself justified, in such a work as this, in taking notice of a professional matter of such importance, had I not been impressed with the idea that the surgeon in question was strictly honest." *

In considering whether the simplicity and the apparent mildness of the procedure should condemn it, we should not forget the fact that many hernias, some of them large ones, are entirely cured simply by the use of a properly adjusted truss; and I will here add, although foreign to this paper, that many more cures might be obtained by this means if surgeons would attend their patients themselves, instead of sending them to persons who are wholly ignorant of the pathology—hence, the proper treatment, of these affections. As one of the most important surgical affections, is it not entitled to the surgeon's most careful personal attention? Were we to turn back the pages of surgical history three hundred years, we would find in the writings of "that famous Chirurgion, Ambrose Parey," that which we should keep in constant remembrance. He relates the case of a priest with hernia, the "biggeness" of which unfitted him for his duties, cured by a truss, and remarks that "it is most worthy of observation and admiration that Nature, but a little helped by art, healeth diseases which are thought incurable." †

If we admit, as we certainly must, that hernia is not infrequently cured by means of the truss, and that, where the sac is *not* returned, nor obliterated, and when there has been nothing to cause adhesion or plugging-up of the canal, we ought not deny that there is a possibility of restoring that canal to its normal size by the operation used by Dr. Heaton.

In reviewing the literature of this subject, we find that the principal operations have been based upon the idea of obliterating the sac, and that it has been incised, excised, ligatured, injected, transfixed, scarified, and treated by acupuncture, all to no avail; for, when removed entirely, a new one readily forms as long as the canal or aperture through which the hernia has occurred is not sufficiently closed to retain the protruding viscera. Heaton believed that these violent procedures were not only dangerous, but useless. In his earlier experiments, he was surprised to see that "whenever the early results were seemingly unsatisfactory because of too little apparent effect, it proved the best as to permanent cure." And he says (p. 37): "I lay it down, therefore, as a cardinal principle in all operations for the cure of hernia, that any inflammation, except the mildest grade, must be carefully avoided."

In performing his operation, Dr. Heaton for many years used an instrument closely resembling the hypodermic syringe, except in the following particulars: it was in every respect stronger, and the needle was made from solid steel wire, bored through the centre with a small drill; and the end, instead of being pointed, is flattened out to a cutting edge, with holes on each side for the exit of the fluid. Dr. Heaton directs that the operator introduce the beak of the instrument into the canal in the following manner: invaginate the right forefinger into the scrotum, and, after locating the external ring, press with the left forefinger, perpendicularly, upon the integument directly over this ring; the left forefinger being at or in the ring—the sac, if remaining out, and cord being held out of the way—the needle is passed quickly into the external ring, and then gently insinuated high up in the canal. About ten minims of the irritant is then distributed over the interior of the canal by ejecting the fluid drop by drop. The patient is then tightly bandaged with a compress over the canal, and for about six days kept in a recumbent position. The irritant used is composed of—

℞ Ext. quercus albæ ..... gr. xxviij.
Ext. quercus albæ ..... fl. ʒ i.
Morphiæ sulphas ..... gr. i.
M.

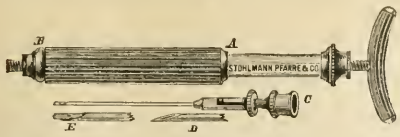
The pain following the operation is slight, and passes away entirely in from two to four hours, without increase in either pulse or temperature.

Having experienced some difficulties in the use of Dr. Heaton's syringe, and especially in being unable to deposit the irritant gradually, owing to the unsteady action of the piston of the syringe, I had one made similar to that shown in the cut. My first modification was in the addition of a screw-piston with crescent-shaped bar at the end of the same, and in having the exterior of the barrel furrowed (*A* to *B*) instead of smooth. The needle was the same as that used by Heaton. In this form I have used the hernial syringe with perfect satisfaction; but, in order to deprive the operation of its only remaining dangers, I have now had constructed what might be termed a trocar-needle. Its construction will be readily understood by reference to the cut on the opposite page: *C* represents the entire needle; *D* represents the cutting-point of the needle exposed; *E* shows it with the point protected in such a manner that no injury can be done to the canal or vessels.

The hernial syringe is used in the following manner: it should be charged by removing the needle

* Fergusson's System of Practical Surgery, 3d Eng. Ed., p. 545.
† The Works of that famous Chirurgion, Ambrose Parey, p. 807. Paris, 1579.

from the barrel and filling the latter two-thirds full; the central part of the needle is then replaced; then, with beak elevated, sufficient of the irritant should be ejected to leave the barrel about half full. By this



means all air is expelled and the perfect action of the syringe is secured. The sheath is now slipped on and it is ready for use. After penetrating the tissues with the cutting-point of the sheath, it is drawn back so that it is perfectly protected, and the beak is then carried well into the canal without fear of injury to its tissue, or to the vessels and nerves which are in close proximity to it. The crescent of the piston is now held firmly in the palm of the hand, and the barrel of the syringe is revolved between the thumb and finger of the same hand. In this manner the needle is revolved and at the same time is gradually withdrawn, thereby traversing the entire length of the canal and distributing the irritant over its interior surface. The after-treatment corresponds in every particular with that given by Dr. Heaton, except that I advocate applying a light truss for at least six months in every case.

The capacity of the syringe is twenty minims.

At a future date I shall give the history of a number of cases operated upon by the foregoing method, and hope that others who perform this operation will make known the results.

116 East Thirtieth Street.

MEDICINAL SPRING WATERS.

By JOHN C. PETERS, M.D.,

new york.

IV.

The ludicrous side of mineral waters is rather conspicuous in those of Krankenheil, or *Disease-curing*, in Bavaria, the principal constituent of which is $2\frac{1}{2}$ grains of bicarbonate of soda in each 16 ounces of the water, aided by $1\frac{3}{4}$ grains of table-salt, $\frac{1}{10}$ of a grain of iodide of sodium, $\frac{2}{100}$ of a grain of silicate of alumina, and $\frac{9}{100}$ of a grain each of sulphate of potash and soda. Of course they are recommended for scrofula and diseases of the skin.

The celebrated Kreuznach waters are generally stated to be strongly iodized, powerfully tonic and stimulant to the lymphatic system, and are used for constitutional syphilis, diseases of the skin, rheumatism, scrofula, paralysis, tuberculosis, and leucorrhœa. They contain scarcely $\frac{1}{8}$ of a grain of bromide of magnesium in each 16 ounces, and $\frac{8}{100}$ of a grain of iodide of magnesium. But they also hold in solution from 72 to 108 grains of table-salt, 13 to 22 grains of chloride of lime, 4 grains of chloride of magnesia, and a little more than $\frac{1}{4}$ grain of chloride of lithium.

The Kronthal waters of Nassau are resorted to by persons suffering from chronic bronchitis and other affections of the lungs, but they merely have from 22 to 27 grains of table-salt in each pint, and 4 to 5 grains of carbonate of lime; but great stress is laid upon the $\frac{5}{10}$ of a grain of carbonate of iron, and the $\frac{2}{10}$ of a grain of carbonate of manganese, which may or may not be found by careful analysis.

The Labassère waters, of the *Hautes Pyrénées*, are also celebrated in the treatment of bronchial and laryngeal catarrh; but the largest constituent of the $3\frac{1}{2}$ grains of solid salts contained in each 16 ounces is $1\frac{1}{2}$ grain of table-salt.

The Landeck waters of *Prussian Silesia*, also strongly recommended for bronchial catarrh, have only $1\frac{1}{2}$ grains of salts in each 16 ounces—sulphate of soda and bicarbonate of soda, of each $\frac{1}{2}$ grain, being the largest constituents.

The Leuk baths of *Switzerland* are said to have a diuretic action, and to be useful in catarrh, swelling of the glands, and skin diseases. The principal component is sulphate of lime or gypsum, $12\frac{1}{2}$ grains in each 16 ounces, and nearly 2 grains of sulphate of magnesia; all the other nine constituents are found in proportions varying from $\frac{1}{100}$ to $\frac{8}{100}$ of a grain.

The Lucca baths of *Central Italy* are widely celebrated for chronic rheumatism and skin diseases. They have nearly 6 grains of sulphate of lime in each 16 ounces of water, and 1 whole grain each of table-salt and of sulphate of magnesia.

The Marienbad or Empress Maria spring waters of *Bohemia* are largely used in abdominal tumors and enlargements, in gravel, gout, derangements of the digestive organs, and glandular swellings. The principal ingredients in the five springs are sulphate of soda (Glauber salts), from 5 to 36 grains in each 16 ounces, with from 5 to 12 grains of bicarbonate of soda, 2 to 15 grains of table-salt, 2 to 6 grains of carbonate of lime, 4 to 5 grains of carbonate of magnesia, $5\frac{1}{2}$ grains of carbonate of iron; that is, from $\frac{1}{12}$ to $\frac{1}{2}$ teaspoonful of Glauber salts in a pint of water, with a little table-salt and soda.

The Paffer and Ragatz waters of *Switzerland*, which are much used on the spot, have only $2\frac{1}{2}$ grains of salts in each 16 ounces, the largest quantity being $\frac{8}{10}$ of a grain of carbonate of magnesia.

The Plombières waters of the *Vosges, France*, so often visited by the Emperor Napoleon III., have only $1\frac{1}{2}$ to 2 grains of salts in each 16 ounces, the largest constituents being $\frac{6}{10}$ of a grain each of silicate of soda and sulphate of soda. They are said to be especially useful for spinal and female complaints.

The Pullna waters of *Bohemia* have no less than 248 grains of salts in each 16 ounces, of which 123 grains are sulphate of soda or Glauber salts, and 93 grains sulphate of magnesia or Epsom salts.

To be continued.

Hay in the Horse-Cars.—The Medical Inspector of the Philadelphia Board of Health has been investigating this subject, and this is what he says: "During wet weather this material makes a very objectionable covering for the floor. When saturated with water it produces cold feet, besides absorbing noxious exhalations. The practice is, among the most of the passenger street roads, to cover the wet hay with a layer of dry during rainy days. This mass is often left in the cars a sufficient time to develop heat and partial fermentation. I asked each conductor as he came to the terminus how often the hay was changed in the cars, and was informed by some that it was changed three times a week, by others frequently, and by two that it was changed once each week. It had been evidently removed since the rain a few days previous to my visit. While not specially objectionable in this instance, nevertheless I consider the use of hay in the cars during the winter detrimental to health. If the committee approve, I will visit the cars of this line immediately succeeding a rainy day."

Progress of Medical Science.

Latent Albuminuria: its Etiology and Pathology.—Albumen, in varying quantities, is frequently observed in the urine of apparently healthy individuals, and opinions have been advanced that its presence is not always evidence of disease of the kidneys, but that it may sometimes be a physiological phenomenon. In opposition to this, Dr. George Johnson, of King's College Hospital, maintains that latent albuminuria—that is, albuminuria unassociated with any other evidence of functional disorder or structural disease—may, by a careful inquiry, be traced back, in a very large proportion of cases, to some probable exciting cause; that the presence of even the smallest trace of albumen in the urine is always pathological; and that the neglect of this pathological condition and tendency, especially such negligence as involves repeated exposure to the exciting cause, may convert a temporary and occasional into a persistent albuminuria, which, sooner or later, though it may be after many years, will result in a fatal disorganization of the kidney. One of the most prolific causes is acute nephritis, which may result from exposure to cold and wet, or may occur in connection with some acute febrile disease. Careful observation in some of these cases has shown that, in spite of apparent convalescence, the albuminuria may continue for months and years. In testing the urine, the influence of food and exercise should be carefully noted, for, it not unfrequently happens that no albumen will be found, except after meals or violent exertion. Latent albuminuria may be caused by exposure to cold and wet without any recognizable attack of acute nephritis. The sudden checking of perspiration after violent or prolonged exertion, while the blood is loaded with the products of disintegrated tissue, may give rise to an albuminuria that may remain latent for an indefinite period, and which, when discovered, can only with great difficulty be traced back to its original cause. Among other causes may be mentioned imprudently prolonged cold bathing, excessive consumption of animal food, alcoholic stimulants, and dyspepsia. The disturbance of the kidney may be secondary to disorders of the liver, and it may occasionally be caused by excessive tobacco-smoking, through the gastric and hepatic disorders occasioned by this habit. There is probably a real etiological relation between mental anxiety and some forms of albuminuria, but Dr. Johnson does not give this cause the same prominence accorded it by Dr. Allbutt. The occasional appearance of a small amount of albumen after food and exercise, or exposure to cold, if not traced to its exciting cause, and if the cause be not such as can be avoided or counteracted, will almost certainly, at no distant period, become a persistent albuminuria; and persistent albuminuria leads on, sooner or later, to fatal degeneration of the kidneys. It is of the utmost importance to impress upon the patient the necessity for a continuous systematic treatment, dietetic, hygienic, and medicinal, adapted to the circumstances of each case.—*The British Medical Journal*, Dec. 13, 1879.

Neurotomy: a Substitute for Enucleation.—The lamentable effects which a sightless eye frequently produces upon its sound fellow has established as a law of ophthalmic surgery that an eye lost from accident, and which continues to be painful, is a dangerous organ. There are many cases, however, in which, in spite of the uselessness of the organ, and the recognized danger of sympathetic affection of its companion, strenuous objection is made to enucleation. In order to gratify the desire of these patients, and at the same time to preserve them from the anticipated evils, Dr. Chisolm proposes division of the nerves entering the eyeball. As is well known, most of these nerves pierce the sclerotic in the immediate neighborhood of the optic nerve entrance, in conjunction with many of the vessels supplying the eye. The operation is performed by making a vertical incision over the tendon of the internal rectus muscle; this tendon is then divided, and the eye rotated forcibly outward by traction on the insertion of the tendon; a pair of strongly curved scissors is next introduced, and all the tissues in the neighborhood of the optic nerve divided. Deep sutures are placed in the severed muscle, the eye closed, and simple water-dressings applied. The hemorrhage is sometimes considerable, requiring a compress and bandage to control it, but it does not usually last long. Owing to the escape of blood into the posterior portion of the orbit, there is generally a good deal of exophthalmia, which, however, soon disappears. In the seven operations performed, recovery has been rapid and the success perfect. Dr. Chisolm thinks he can confidently recommend this operation to the attention of the profession, as possessing, in many cases, all the advantages of enucleation without the disadvantage of the subsequent use of an artificial eye.—*Reprint from the Va. Medical Monthly*, Nov., 1879.

Effect of Tincture of Arnica on the Skin.—M. Donaud has reported to *La Société Médicale de Bordeaux* two cases of remarkable susceptibility of the skin to the action of tinct. arnica. The pure tincture had been applied for insignificant injuries, when vesication and subsequent inflammation were developed. This action of the drug has already been noticed by a German surgeon, and in the discussion following the reading of the paper, MM. Bourrier, Demons, and Armaignac said they had seen similar cases.—*Le Courrier Médical*, Nov. 29, 1879.

Spermatic Colic.—Under this title, M. Reliquet reports a curious case, occurring in a man twenty-five years of age, in which he had diagnosticated prostatic tubercle, and which presented the following symptoms: violent pain during coition; painful sensations in the perineum, with frequent desire to urinate while riding in a carriage; frequent and violent emissions from the urethra of a liquid analogous to the spermatic fluid. Rectal examination revealed an inequality of the prostatic lobes, the right lobe presenting a well-defined swelling, which was continuous posteriorly with the vesicula seminalis. Pressure with the finger was painful, and induced a desire to urinate. A sound was introduced into the urethra and the tumor compressed between it and the finger. This manœuvre caused the expulsion through the urethra of a grayish mass, resembling vermicelli, and which examination showed to consist of altered spermatozoa, and mucus. The spermatic colic, the retention of the semen in the ejaculatory duct, was the cause of all the symptoms. After repeated sounding, and further evacuation of the retained mass, the tumor disappeared and the reflex troubles of micturition were relieved.—*Journal de Médecine et de Chirurgie*, Dec., 1879.

Growing Fevers.—Certain unexplained troubles peculiar to the period of development, usually com-

prised under the vague name of *growing fever or sickness*, have been the subject of careful investigation by M. Bouilly. The following are the conclusions to which he has arrived:

There are among young subjects certain fevers which are caused by sudden attacks of congestion in the neighborhood of joints, in the epiphyseal zone.

These attacks may be apyretic, announcing themselves only by pain and the increased size of the joint.

This is the mildest form of the osteomyelitis of children and youths—the juxta-epiphyseal osteitis of Gosselin, and may explain the so-called *growing fevers*.—*Gazette Médicale de Paris*, Nov. 29, 1879.

Carica Papaya.—The physiological action of the carica papaya, or papaw tree, has been made the subject of investigation by Dr. Moncorvo, of Rio Janeiro. The juice of the fruit, obtained in small quantities by expression, was the portion experimented with; but, owing to the difficulty of collecting more than a very small quantity, and to the rapidity with which it undergoes fermentation, no satisfactory analysis of it has as yet been made. The most curious effect of this drug is exhibited in meat submitted to its action. Finely chopped meat, macerated in a ten per cent. watery solution for twenty-four hours, is entirely dissolved, and exhales a very strong and insupportable ammoniacal odor. If, instead of this lengthy maceration, boiling for five minutes be substituted, the disintegration is almost as complete, the meat being reduced to a pulpy consistency. Albumen, boiled for three minutes in a solution of papaya juice, is first coagulated by the heat, and then dissolved. On starch, apparently, no action is developed.—*Journal de Médecine de Bordeaux*, Dec. 6, 1879.

A New Test for the Amyloid Substance.—The new reagent employed by Weiss for the detection of amyloid matter is safranine. It occurs in commerce as a dark red powder, and is obtained by the action of nitric acid and arsenic on impure aniline. It is very soluble in alcohol, less so in water. Sections submitted to the action of a watery solution of this reagent show, under the microscope, a beautiful orange-yellow staining of the amyloid substance, while the rest of the specimen is of a beautiful rose-color. If the safranine be dissolved in water acidulated with acetic acid, the whole preparation presents a uniform rose tint—a phenomenon that Weiss is unable to explain. The coloring takes place very rapidly; the connective tissue is less tinted than the epithelial cells, and the cells less than their nuclei. Thick tissues color well; those which have been hardened in alcohol still better; but not those that have been treated with chromic acid, or with the chromates. Preparations thus colored may be preserved for a long time in a saturated solution of acetate of potassa. A few grains of safranine dissolved in a glass of water are sufficient, in many instances, to color microscopic preparations.—*Lyon Médical*, Dec. 28, 1879.

Treatment of Phthisis by Inhalations of Benzoate of Soda.—Prof. Rokitansky is disposed to think very highly of this treatment, although he is as yet unprepared to publish the results of his observations. He thinks that the method in which the inhalations are practised is of great importance, and that they should, therefore, be always taken under the supervision of the physician. In order that the spray may find free access to the throat and lungs, he directs the patient to draw the tongue forward or to hold it down with a spatula, and then to take deep inspirations until coughing is excited. The inhalations are repeated until the cough is no longer followed by expectoration. He assumes that the tubes are then cleared of mucus, and that the medicine comes into direct contact with the mucous membrane. The inhalations are practised morning and evening, and the patient is kept for an hour afterward in the room, the air of which has become more or less impregnated with the benzoate of soda. As Buchholz and Klebs have shown that this drug destroys bacteria with certainty only when administered in the proportion of $\frac{1}{1000}$ of the weight of the body, Rokitansky makes his patients inhale daily one grammo of the drug (in a five per cent. solution) for every $2\frac{1}{2}$ lbs. of their weight. He attributes to this medication, first of all, a destructive action on bacteria; and, secondly, a mechanical action on the pathological secretions, which are rendered more liquid and are more readily removed from the air-passages. This results in an amelioration of the catarrhal symptoms, and perhaps prevents the transformation of the secretions into caseous masses. Further, he believes that the forced inspirations and expirations dilate the air-vesicles and counteract the compression of the vesicles by interalveolar tubercular masses. He is convinced, moreover, that the benzoate of soda, when used in this manner for a long time, acts also as a febrifuge. Of course, he combines with the inhalations the usual hygienic and dietetic treatment.

Dr. Schnitzler, of Vienna, on the other hand, is inclined to be skeptical with regard to the value of these inhalations. For the sake of experiment, he made a large number of patients inhale a five per cent. solution of benzoate of soda, which had been colored with a few drops of aniline, or alternately solutions of tannin and perchloride of iron, and, on examining them afterward with the laryngoscope, found the mouth and pharynx uniformly discolored by the solutions, while the larynx and trachea presented only a few isolated discolored spots. From this he argues that atomized liquids do not penetrate to any extent into the bronchi, and that the marvellous effects attributed to the benzoate of soda, if not entirely illusive, must be ascribed to the volatilization by heat of the benzoic acid, which can then undoubtedly penetrate into the smallest tubes. Hence, he claims that it would be more logical to employ directly the volatile benzoic acid for the inhalations, and that if any special curative action be expected from the benzoate of soda, it would be preferable to administer it internally, when the same results could be obtained with much smaller doses. He closes his paper by recommending, as an antiparasitic treatment of phthisis, the inhalation and subcutaneous injection of carbolic acid, a treatment which he has employed for three years with relatively very favorable results.—*Annales de la Société Médico-chir. de Liége*, November, 1879.

Tuberculosis.—Professor Cohnheim declares himself in favor of the view that all tubercular processes are infective in origin. Dr. Schueppel thinks that bacteria underlie them, and hence the appropriateness of all anti-parasitic remedies.

Treatment of Gastric Inflammation.—Injections of cold water into the rectum, according to Winternitz, rapidly lower the temperature of the stomach. It is inferred that such enemata may be of service in some gastric disorders.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 7, 1880.

THE EDUCATION OF THE GENERAL PRACTITIONER.

A very valuable report has lately been presented by a committee of the Metropolitan Branch of the British Medical Association. This committee was empowered to investigate the question of medical education. The members consisted of prominent medical teachers and general practitioners, Dr. Andrew Clark and Messrs. Savary, Bryant and Wood being among them.

Circulars were sent out to a large number of medical men, and over four hundred replies were received to certain questions that were propounded. Some of the details deserve recording.

The first question was: "Is it desirable that intending medical students should pass an examination in the elements of botany, physics, and inorganic chemistry prior to admission to the regular curriculum?" To this question ninety per cent. of teachers and ninety-six per cent of general practitioners gave an affirmative answer.

The second question was: "Is it desirable that a certain period, previous to admission to a medical school, should be spent with a general practitioner in the form of articled pupilage?" The answers to this question showed much diversity of opinion. About three-fourths of the teachers were opposed to articled pupilage in any form, and about the same proportion of general practitioners were in favor of it. The argument given by the teachers was that the slight amount of knowledge picked up during an apprenticeship only made the student flippant and conceited, and unfitted him for subsequent systematic work. The arguments of the practitioners were based on the fact that they generally found medical students deficient in tact, in the art of prescribing, and in handling the patients of whom they were put in charge.

Nearly ninety five per cent. of those questioned believed that the age of eighteen years should be attained before the student enters a medical school. With the four years' course in English schools, this would make the youngest age for graduation twenty-two.

The fourth question was: "Do you approve of the introduction of an examination in elementary anatomy and physiology at the end of the first year of medical studies?" Strange to say, only a small majority favored this plan, it being urged that it would press too severely on provincial students, and keep up a harassing state of nerve tension. The committee, however, recommended that some such examination ought to be held, as it would be a stimulus to work during the first year.

With this conclusion we heartily agree, as the first year is, under the ordinary plan, generally given up to testing various brands of tobacco or the toxic properties of alcohol, and in the easy and comfortable absorption of such medical lore as a semi-soporific condition during lecture hours will take in.

The value of graded courses and annual examinations is now very generally admitted, and is adopted more extensively every year. Even in the two colleges in this city which do not have a graded course, an examination in anatomy and physiology is held, which first course students can take if they choose. The great drawback to such examinations is not the nervous tension from overwork and anxiety, but the fact that the student, having passed in these branches, thereafter neglects them and graduates often in the greatest ignorance of the studies with which one or two years before he was tolerably familiar. We have often been told, by students who had studied under the graded course system, that they were allowed to graduate, although they had quite forgotten their anatomy, physiology, and chemistry. It cannot, of course, be otherwise, under the usual graded plan. But there is an easy remedy.

The yearly examinations should embrace more of the branches each year, and the final examination should include all. If a medical student cannot carry enough of all these studies in his head at once to pass a degree examination, let him take up some less trying profession. Yearly examinations are stimulating and beneficial; but it is hardly right to graduate students who have not been examined for two years in, for instance, so easily forgotten yet essential a science as anatomy. As regards the other questions submitted by the committee, we believe that the views expressed by the majority are sound, and that the profession in this country will very generally endorse them as applicable to our own schools. We have not had for many years any system of articled pupilage, nor would it be possible to introduce such a system in this country. Nearly every medical student, however, especially if from the country, has his

preceptor, with whom he studies and rides during the summer or in the intervals between the lecture courses. Perhaps he is sometimes made supercilious and over-confident by this slight taste at the Pierian spring; the practice is, however, a very beneficial one. Indeed, so small a per cent. of students get any hospital or dispensary practice, that this plan of going out with the preceptor is often absolutely essential.

We must, in conclusion, commend the method which the committee adopted of sending out among the working and teaching members of the profession for opinions on the subject of medical education. It not only secures information that can be relied on, but it excites a wider interest among medical men concerning a subject which is vital to the growth and standing of the profession.

AN ADVOCATE FOR FAST EATING.

Dr. J. F. Hibberd, in the *St. Louis Journal*, advances a number of reasons in favor of rapid eating rather than slow. He claims that in his experience those who "bolt" their food are the healthy members of society, while those who eat slowly and masticate thoroughly are always dyspeptic and sickly. His explanation is, that well-masticated food passes from the stomach almost immediately and before it has been acted on by the gastric juice, while large pieces of food are retained until softened and dissolved by the digestive process.

This reasoning of the doctor is fallacious. Those who bolt their food are healthy because only the healthy can adopt so disgusting a habit. When they begin to get dyspeptic from their immoderation, they have to eat more slowly. The general experience of physicians for many years has been that rapid eating is a cause of dyspepsia. This opinion is in accordance with physiological facts. In regard to the present "new view," it is well enough to allow the medical imagination to work itself off occasionally in startling hypotheses. When such a hypothesis, however, violates good breeding and common sense, and would revert us all to a carnivorous type, we believe it should not be quoted without a condemnation.

THE BILL FOR THE CREATION OF A STATE BOARD OF HEALTH.

The advantages to this State of a board of health have often been presented by us, and are now generally acknowledged by every one. There have always been, however, some practical difficulties in the way of establishing such an organization. The danger of State authority conflicting with local, has been especially felt with us, as it has been in Pennsylvania. But this difficulty has never appeared insurmountable, and we are very glad to announce that a bill has at last been prepared and introduced into the legislature, which seems likely to secure the desired harmony between State and city authority.

This bill was drawn up by the attorney of the New York City Health Board. It has received the approbation of that Board, and of a number of prominent sanitarians and medical men. Arrangements have also been made to have it energetically pushed at Albany, and there is a reasonable hope of its passage.

The bill provides for a State Board of Health, composed of nine members. Three of these, to be called Commissioners of Health, are to be appointed by the governor, with the consent of the senate. Of these three, two are to be physicians of at least seven years' practice. These three, together with the Attorney-General, the State Engineer, the Health Officer of the Port of New York, and three other persons, one of whom must be a member of the New York City Board of Health, and the other two, members of some regularly organized city health board, are to constitute the "Board of Health of the State of New York." The first three commissioners are to serve for three years. The term of service for the remaining six will depend upon the length of their holding their local offices.

We may remark concerning this part of the bill, that it leaves a possibility of their being but three physicians on the State board, and under the present administration two of these may be homœopaths. Such a contingency is an undesirable one. It is the medical profession which will contribute most to the work and practical usefulness of the board. That profession, therefore, should, with the civil engineer, make at least a majority of the nine commissioners.

The board is to have power to elect its officers and enact by-laws. It can also elect a secretary from its own members, or, if it wishes, from outside, thus increasing the number of members to ten. This secretary is to be also the executive officer. He is to receive a salary of $3,000 a year. The other members serve without pay.

The duties of the board, as laid down, are to take cognizance of the interests of health and life among the people of the State. It is to investigate the causes of diseases, especially of epidemics. It is to examine into the effect of localities, employments, and other conditions, upon public health. It is given general supervision over the registration of births, marriages and deaths; the secretary of the State board being made the superintendent of registration of vital statistics for the whole State. Local boards must forward to him reports of all their work. The governor may, at any time, require the State board to investigate alleged nuisances, and, upon a report, the governor takes action or not, to have such alleged nuisance abated.

Should any sanitary matter that properly comes under the jurisdiction of a city health board be thus investigated by the State, one of the members of that

Board may be selected to meet the State commissioners, such local health officer is empowered to take part in the deliberations, but can have no vote. This is the plan by which it is hoped to make the local and State organizations work harmoniously together. The governor can order the State board to investigate a nuisance anywhere; and if pronounced a nuisance, he can order it abated, even if it be in city limits, and a matter to which local authorities should attend. The only check which municipal authority has upon State interference is the voice in council, but not the vote, of one of its health officers. The authority given the State board is thus quite large. It is not likely, perhaps, that it will be abused; still, this is a point which should bring out full discussion.

The State Board is further empowered to engage experts to make such scientific investigations as may be deemed necessary; it is also authorized to examine, when desirable, any public structures, as well as the grounds or plans thereof. The sum of $15,000 is appropriated to carry out the purposes of the act.

It will be seen that the proposed law is a very comprehensive one, and gives power to investigate, supervise, and correct all matters pertaining to the health and physical condition of the citizens of the State. It may appear that more power is granted than a new organization should possess, especially in the matter of encroaching on the field of local health boards. We do not care, however, to discuss now the special provisions of the bill; we believe that in most particulars it is an excellent one, and will create an efficient and useful State organization.

It is our duty, as a medical journal, to urge the profession to give this bill, or some modification of it, its countenance and help. A State board of health is necessary for many reasons. We need it to complete our registration of vital statistics. We need it also for the impulse it will give towards creating local health boards; a result that can be reckoned upon with certainty from the experience in Massachusetts and other States. There is need of a sanitary power which will have a wider reach than any city or county authority possesses. There are many nuisances in one county which affect chiefly the citizens of another. There are swamps and miasmatic centres created by railroads, as in the case of the Hudson River Railroad, which, in many places, has stopped the proper drainage of the soil. The pollution of streams and sources of water-supply often cannot be prevented by local authority alone. The various unsettled questions of inter-State quarantine, of epidemiology, and the more special matters of sanitary architecture, the disposal of sewage, and the value of disinfectants—all these can be greatly aided by a proper State organization.

Finally, we can hardly urge too strongly upon the medical profession the importance of paying serious attention to the subject of preventive medicine. It is to form a most important factor in the civil life of the future. The question of the sanitary organization of nations will call out the best powers of statesmen and men of science. If physicians ignore this question, it will ignore the physicians, and their position will be lowered, their usefulness narrowed. The profession should, therefore, give its countenance to the matter heartily. The annual mortality throughout civilized countries is over two per cent. It should be less than one and a half. Preventable diseases cause one-fourth more deaths than need be. These are matters for the medical profession to remember and stir themselves to remedy. We must accept the fact that the province of the doctor is not alone that of healer, but of health-officer to the family and the community. He must seek for hygienic as well as therapeutic triumphs.

With such an understanding and purpose, there will be sure to accrue an additional lustre and dignity to the profession.

There are many things now in the uncertainties of therapeutics, the passions of over-competition, and the pretensions of charlatans, that tend to drag us down as a profession. As physicians, then, we cannot afford to ignore the opportunities offered us in fostering preventive medicine. Such efforts will be repaid, not only in the practical good accomplished, but in an elevation of the professional character, and in an increased consideration from our fellowmen.

MEDICAL MEN AS WRITERS.

THERE has been of late a tendency to get contributions from medical men in leading popular periodicals. It was only a year ago that a whole phalanx of eminent English physicians appeared in the *Contemporary Review* and delivered themselves on the subject of alcohol. It was an instructive, although somewhat incongruous performance. Since then Sir Henry Thompson has attracted public attention in the *Nineteenth Century* to the subject of food. Dr. Maclagan has been an advocate of the germ theory in the same journal; Dr. Althaus and Prof. Ferrier have given popular expositions of the functions of the brain, and Sir James Paget has related the history of anæsthesia.

On this side of the water we find the profession less frequently represented in our monthlies. Nevertheless, there have been some admirable articles in the *North American Review* by Dr. George M. Beard, and a recent article by Dr. J. S. Billings in the *International Review*, will attract attention. But most of our prominent monthlies aim at high effects in art, and are very shy of anything that looks statistical and scientific.

We can find in the increasing number of popular articles on medical and allied subjects, however, an

evidence that the scientific standing of medicine is rising in the general opinion of mankind, as it is in fact. The position of the physician has been said to be the measure of a nation's civilization. It is certain that with the increased intelligence of a people more will be demanded of the medical man, and this demand, history shows, has always been responded to.

THE PRESENTATION OF THE "LOVING-CUP" TO THE ACADEMY OF MEDICINE.

The presentation of the "loving-cup" to the Academy of Medicine was very naturally the cause for considerable jubilation by the large number of Fellows present on the occasion. The circumstances attending the bestowal of the gift are pleasant to contemplate, and carry with them a significance which must not be lost on the profession. It seems to be a beginning of better things in showing that the wealthy and cultivated portion of the community represented in Mrs. Astor are willing to bear substantial testimony to the true worth of the profession, and to express a kindly sympathy in the purposes of that work which bears "so large a share of care and sacrifice."

The sentiment engraved upon the cup is most appropriate, and, we trust, will find a response not only in the heart of every Fellow of the Academy, but in that of every member of the profession throughout the country. If all medical communities could lift the "loving-cup" above the little prejudices and jealousies of professional competition, in how much clearer atmosphere the usual pledges could be offered, and how often would "peace and love be multiplied unto us"!

RANDALL'S ISLAND HOSPITAL ABUSES.

The sensational articles which appeared in last Sunday's and Monday's issues of the *Herald* with reference to the management of Randall's Island Hospital, are so manifestly untrue that we consider it a mere matter of justice to the Medical Board of the Hospital and to Dr. Howard, the Medical Superintendent, to call the attention of our readers to the subject. To those who know the condition of the Island at the present time, and what it was only two years ago, the change for the better is a subject of remark. The Medical Board, numbering seven members, has entire control over all the hospital buildings, and, like similar city hospital boards, is faithful and conscientious in the discharge of its duties.

The Infants' Hospital is a large, well lighted, well ventilated building, which, in regard to its sanitary condition, will bear very favorable comparison with similar institutions. In fact, it is probably better suited for its purpose than any other infants' hospital in the city.

The case of scalding upon which so much stress is laid by the *Herald*, was the result of an accident, which was unavoidable under the circumstances. At all events, the cause of death in this case (acute parenchymatous nephritis) had evidently no relation to the burn, if the results of surgical experience are to be relied upon.

The account of the case of the idiot boy, Joseph Leisch, appears to have been evolved out of the inner consciousness of the ubiquitous reporter. The facts simply are, that the boy was admitted to the Idiot Asylum on a regular commitment from the Superintendent of the Out-door Poor, and was then sent to the idiot school. The boy was never examined by Dr. McDonald, but when the attention of the regular visiting physician for nervous diseases was called to the case, the boy was pronounced to be *not* an idiot, and was sent to the hospital. This was done contrary to the protest of two of the teachers of the idiot school, which was not at that time under the jurisdiction of the Medical Board.

It is a very suspicious circumstance, to say the least, that the idiot school, whose management is now being subjected to an investigation by the Medical Board, should be the recipient of a glowing eulogium by the discerning *Herald* reporter, and appears to indicate an animus which can be located without much difficulty.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 15, 1880.

FORDYCE BARKER, PRESIDENT, IN THE CHAIR.

The Academy was called to order at 8.15 P.M., and the minutes of the last stated meeting were read by the Secretary, DR. H. T. HANKS. The PRESIDENT introduced Dr. Philips, ex-President of the Ohio State Medical Society, and Dr. Naechtel, of Paris, France, and invited them to seats on the platform.

DR. J. LEWIS SMITH then read a paper on

PLEURISY AND EMPYEMA IN CHILDREN, AND ITS TREATMENT.

Formerly, idiopathic pleurisy was supposed to be rare in children, but greater precision in examination, and more frequent autopsies, have enabled the profession to correct that error, and it is now known that primary pleurisy is not infrequent in young children, even in infants. In the New York Foundling Asylum there occurred, in seven consecutive months, 31 cases of bronchitis, 21 cases of pneumonia, 3 cases of tuberculosis, and 11 *cases* of *primary* pleurisy; that is, independent of extension of inflammation from the lung. Reference was then made to the diseases for which pleurisy is mistaken, such as pneumonia, intestinal irritation, remittent fever, etc., and cases were related. Reference was also made to the fact that pleurisy occurs more frequently in the wards of public institutions than in families, and during the prevalence of scarlet fever it is more common than at any other time. Of 404 consecutive patients in private practice, two had primary pleurisy, which was

regarded as about the usual proportion in family practice, except when scarlet fever prevailed.

Causes.—The most common cause is taking cold. Cachexia rendered children especially liable to contract the disease. It occurred more frequently among the city poor than among those who are in comfortable circumstances. Pleurisy is not rare in new-born infants, and the cause is not always apparent. A case of double pleurisy, without disease of the lungs, with a small quantity of pus in each pleural cavity, occurring in a child one month old, was related, and yet the cause was obscure. Pleurisy following scarlet fever is very nearly always suppurative. Pleurisy is produced by discharge of material into the pleural cavity from an opening in the lung occurring in connection with *hypostatic pneumonia*, a cause which the author of the paper had not seen mentioned by any writer upon diseases of children. The order was hypostatic congestion, or pneumonia, disintegration of lung-tissue, perforation, introduction into the pleural cavity of morbid material, suppurative pleurisy. Another cause is indolent pneumonia, circumscribed, in the posterior part of the lung, formation of abscesses not larger than a pin's head, opening and discharging into the pleural cavity, producing suppurative pleurisy. Cases were related.

Abscess in the chest-wall and opening into the pleural cavity was mentioned as another cause. Pleurisy attributable to traumatic cause rarely occurs in children.

Anatomical Characters.—They are the same which occur in inflammation of other serous surfaces. The fluid is usually in the posterior, inferior, basilar portion of the pleural cavity. In empyema, draw a line from the axilla somewhat forward and downward, and that portion of the cavity in front is occupied by compressed lung, and that posterior to it by fluid. The lung is crowded upward, inward, and forward by the pus, and that is an important point with reference to the operation of thoracentesis, which should be performed a little forward of a perpendicular line through the angle of the scapula and between the seventh and eighth or eighth and ninth ribs. Displacement of organs does not occur to the same extent as is seen in adults. In four cases, general pericarditis had been found as a complication from extension of the inflammation; and in one case localized peritonitis was developed by the same cause, affecting not only the under surface of the diaphragm, but a corresponding localized surface upon the liver.

Symptoms.—Those especially noteworthy were the following: in some cases the attack is not accompanied by the usual symptoms of pleurisy. Frequently the pain is ascribed to colic. At first the temperature may not be high, but ordinarily it soon rises to 102°, 103° F., or higher. The fever of pleurisy continues longer than that of pneumonia. The pulse continues rapid until convalescence is well established. The pain is referred to the thorax less commonly than in adults.

Physical signs in patients under three years of age: *Inspection.*—Accelerated respiration; bulging of the chest-walls not so frequent as in older children or in adults, and is hardly appreciable either by sight or measurement. That fact was explained on the supposition that atelectasis of the lung occurred to an extent sufficient to compensate for the space occupied by the fluid. *Palpation.*—The signs obtained by this relate chiefly to fremitus and displacement of the heart. *Percussion.*—Resonance as in health during the first hours of the disease; subsequently, usually between the second and fourth day, dulness corresponding with the amount of fluid in the pleural cavity. Adhesions are frequent, hence, change in position could not be made of so much avail in determining the presence and quantity of fluid as in the adult. *Auscultation.*—Absence of respiratory murmur does not occur in infants, under the same conditions, so uniformly as in adults. Respiration can, in most instances, be heard through the liquid, either coming from the same or the opposite side of the chest. Instead of absence of respiratory murmur, a distant, finely vesicular murmur is sometimes heard, probably communicated through the fluid, or it is bronchial or broncho-vesicular, produced in the bronchial tubes upon the affected side. This is especially likely to be present in children under three years of age.

Differential Diagnosis. The introduction of the hypodermic needle is the crucial test, and, even should the case be one of pneumonia, no harm would come of introducing it between the eighth and ninth ribs, a little below the angle of the scapula and slightly forward. As a rule, if pleurisy is present, fluid can be so removed and its character ascertained.

Treatment.—The objects are to reduce the inflammation and diminish the exudation. Loss of blood was injurious in secondary pleurisy, and also when the quantity of exudation was large. It was adapted only to primary pleurisy at the very beginning, rarely under the age of six months, and by leeches only. The leeches were advantageously followed by a poultice composed of one part of mustard and sixteen of flaxseed, to be covered with oil-silk and changed once or twice in twenty-four hours. Blistering was not advisable in the early part of the disease, for at that time it increased rather than diminished the inflammation. Cold applications were not advised. In the first stage a cardiac sedative usually was of service, and the tincture of aconite root was suggested; quinine in sufficient doses to depress the fever; digitalis to control the rapid action of the heart. Opiates were regarded useful in the first stage of the disease. A favorite prescription contained Squibb's fluid Dover's powder, tincture of aconite root, and balsam of tolu. When the fluid is pus, operative measures for its removal are indicated; if sero-fibrinous, no operative interference, perhaps. Hydragogue cathartics, as a rule, are depressing. He had not known marked benefit to follow the use of sudorifics. He had no personal experience in the use of jaborandi, and did not care to be the one to test its efficacy. Acetate of potash and iodide of potassium were recommended as diuretics. Digitalis was regarded as especially beneficial when the pleurisy is complicated by pericarditis, its action being that of a cardiac tonic rather than a diuretic. Acetate of potash half an ounce, infusion of digitalis six ounces, and a teaspoonful every three hours for a child under five years of age. The diet should contain only a moderate amount of liquid. Syrup of the iodide of iron could be used in place of iodide of potassium when the patient is cachectic, and compound iodine ointment may be of service. If the appetite is good, and symptoms not urgent, not much active treatment is required.

Thoracentesis.—The admission of air in moderate quantity into the pleural cavity produces no injurious consequences if the pleural surface is in a healthy condition. If air is admitted into a cavity containing sero-purulent fluid, putrefactive changes will follow; its admission consequently does harm. Dr. Smith then referred to the indications for thora-

centesis, as given by Dr. Bowditch of Boston, and by the late Dr. Anstie in Reynolds's System of Medicine. To these he added his own rules, which were to always use a trocar and aspirator combined. The liquid should not be removed through a canula having a sharp point, for the point will injure the lung. A puncture five-eighths of an inch deep is sufficient to penetrate the purulent cavity, when the trocar can be detached, the aspirator attached to the canula and the fluid removed. When the liquid is sero-fibrinous a single aspiration is usually sufficient. In empyema a fistulous opening should be established. The method was to remove the liquid, wash out the pleural cavity with carbolized water, temperature 100° F., strength 1–100, and then introduce threads by means of an instrument he has devised for that purpose, and allow them to remain. The washing out to be done *but once*, unless the pus be fœtid, when the cavity should be washed out every second day. By frequent washing out of the pleural cavity we interfere with Nature's method of effecting a cure.

The paper being before the Academy, Dr. F. P. Kinnicutt referred to points in the symptomatology of pleurisy. The friction-sound, as heard in children, very rarely has the harsh, grating character which it has in adults, but it is rather a fine crepitation, differing only from that of pneumonia in being less firm and more superficial. The pain in the abdomen, he thought, could be referred to an affection of the intercostal nerves; the pain being felt at their terminal extremities, hence referred to the abdomen low down.

Dr. A. C. Post thought that it was highly desirable in purulent collections in the pleural cavity to make a free incision with scalpel or bistoury, rather than attempt removal of the liquid by means of the aspirator needle or trocar. In purulent collections there is frequently great viscidity of the fluid, so that it cannot be drawn very perfectly through the largest needle. He had known of cases in which, from a free incision allowing the cavity to empty itself as fast as the pus is formed, the most marked relief had followed when the relief following drainage through a smaller opening had been imperfect. In children it is especially desirable that a free incision should be made, so that none of the purulent matter is retained in the pleural cavity.

Dr. Beverley Robinson agreed with Dr. Post regarding the radical operation. He also agreed with Dr. Smith that too frequent washing out of the plenral cavity is not advantageous. He had seen fatal terminations take place while injections were being made into the chest. He always used the thoracentesis needle as soon as there was evidence of fluid in the pleural cavity, and had never seen any unfavorable results follow its use. He doubted whether it is a serious evil even to puncture the lung, if the needle is small. He had left the needle in the chest in two cases, without unhappy consequences. He used medicinal treatment only as an aid to aspiration.

Dr. E. H. M. Sell spoke of good results obtained by free incision in empyema in Paris, in 1877. He believed the iodine treatment efficacious. Thoracentesis was well when medicinal treatment failed. Chalybeate tonics and digitalis were serviceable, and he had also seen good results follow the use of asclepias and gelsemium.

PRESENTATION TO THE ACADEMY.

The President—It will be remembered that on the opening of this Library Hall, when the programme of the evening had concluded, all present were invited to go below and partake of the "loving-cup." A regret was expressed that the loving-cup, of itself, was only glass, instead of such material as is generally made use of, in such ceremonials, in England. Soon after the report of the meeting was published in our city newspapers, it will also be remembered that the Academy received, through its President, a letter containing a check for $200 for its library, from a lady whose earnestness in every good word and work, and whose interest in and sympathy with all

the benevolent labors of our profession is universally known and acknowledged in this city. It is not merely for the sake of saving my voice, but also for the purpose of doing better justice in its reading, that I now ask Dr. Thomas to read this letter, which I have just received for the Academy.

Dr. Thomas then read the following letter:

Dear Dr. Barker:—I beg your acceptance, as President of the New York Academy of Medicine, of the accompanying cup, which, if you will oblige me by using as a "*Loving-Cup*" on the occasion of your next anniversary meeting, will owe all of its grace to words spoken by yourself in the early Autumn. It comes to you as a messenger of a true sympathy in the purposes of the Society, and it is engraved with words that, I believe, touch equally your *ideals* for its work and your *personal* feelings toward all of your associates; and I shall feel a sincere gratification if its occasional use—in agree-

ment with such kindly sentiments may procure a moment's pleasure to those whose days hold, necessarily, so large a measure of care and sacrifice.

Always, my dear Doctor, with faithful regard,
Your friend,
AUGUSTA ASTOR.

THE PRESIDENT—The cup, to which reference is made in the letter just read by Dr. Thomas, I now shall bring before you. Its beauty of design, conceived by the donor of the gift, and its perfection of artistic finish, are worthy of the graceful language in which it is offered to us. I am now most happy to offer it for your inspection. Its surface is ornamented by the acacia, symbol of friendship and love. On the front is the seal of the Academy, its motto, and the head of Hippocrates. Above, is the name of the President and the date of his election, with spaces left for the names of his successors; while on its upper part is engraved a sentiment in which I am sure that all of us will most heartily sympathize. When we adjourn, I shall ask you all to make use of this "loving-cup" in the room below. It has already been consecrated by the lips of woman, the aroma of which, let us hope, will ever remain to perpetuate the beautiful sentiment engraved upon it: "May peace and love be multiplied unto us."

DR. LEWIS A. SAYRE—Mr. President: It seems to me that this is an unusual occasion, and that it deserves more than ordinary attention. I think we should not let this presentation pass without proper recognition. When I look back to my first visit to New York, there seems to be such a contrast between the feeling of the people toward the medical profession at that time, and that exhibited by the evidence shown to us to-night by this token of respect, that it is little less than marvellous. I recall very well, coming, as I did in 1839, from Kentucky, asking some half a dozen men—respectable-looking men of New York—where the Medical College was, and none of them could tell where it was, and sent me down to Barclay Street, not knowing that it had been removed to Crosby Street some three years. That was pretty much all the interest they felt in those days in the study of medicine. My old friend here to the left, from Boston, was just saying to me that in Boston it was customary for wealthy persons to give to colleges, to donate to public institutions, to endow professorships, and that it was the case in small villages for the people to interest themselves in professional behalf, and that they directed their attention to it; but in New York the great commercial interests attract so much attention that the profession of medicine is lost sight of. Generous the people are in their distributions to hospitals, all of which is very well, but this is the first instance where a person, just from a hint that our loving-cup was not stronger than glass, has entered and supplied the want, and I regard it as an indication that the wealthy citizens of New York are becoming interested in our profession. I look upon it as an era, as an opening up to the hearts of the wealthy citizens of this great emporium, and I believe that all we have to do is to make our wants known to the wealthy and cultivated people of this city, and we can command what we wish. I beg leave to offer the following resolutions:

Whereas, Mrs. John Jacob Astor has kindly presented to the New York Academy of Medicine this magnificent "Loving-cup," as an evidence of love and respect for the profession and of her regard for the President of the Academy; therefore,

Be it resolved, That the New York Academy of Medicine tender to the donor an unanimous vote of thanks for her generous gift, which will be preserved by its members as a perpetual memorial of her appreciation of the profession.

Resolved, That a copy of this preamble and resolutions be engrossed, signed by the President and Secretary, and transmitted to Mrs. John Jacob Astor.

DR. T. GAILLARD THOMAS—I second most cordially, Mr. President, the resolutions just offered by Dr. Sayre. Let us recognize with pleasure a new era in the closer accord between medicine and the community in which we live, as evidenced by this graceful and generous gift. It is the olive-branch held out to us by an appreciative public, and it comes to us through the hand of a noble woman. As Dr. Sayre has said, it marks a new period in the history of our guild in New York. Let us hope that it will prove an earnest of the future, and let us mark our appreciation of it by an unanimous vote of acknowledgment.

The resolutions were unanimously adopted, and, after the transaction of unfinished business, the Academy adjourned to partake of the loving-cup.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Jan. 14, 1880.

DR. E. L. KEYES, PRESIDENT, IN THE CHAIR.

EXTRAVASATION OF URINE.

DR. BRIDDON presented several specimens, the histories of which were furnished by Dr. Wetmore, House Surgeon to the Presbyterian Hospital. The first of these was the genito-urinary apparatus of a male patient, aged fifty-six years, who was admitted to the Presbyterian Hospital December 22d, suffering from the effects of extravasation of urine.

Eight days before he had been in perfect health. No history of gonorrhœa or injury. At that time he was taken with a severe chill, followed by fever, headache, and retention of urine, which was relieved by a flexible catheter. Four days after he had another severe chill, with fever and retention of urine. Next morning noticed swelling of penis and scrotum; in an short time the swelling extended up on to the abdomen. Catheter passed eight hours after the extravasation began, by his family physician, and some water drawn off. This was repeated three times a day, and water drawn each time.

On admission, three days after extravasation, the penis, scrotum, and perineum, were enormously swollen, the swelling extending as high as the umbilicus. Temperature 99½; pulse, 100; respiration, 40; pain in penis and scrotum. Patient etherized, and two incisions made, one on each side above Poupart's ligament, when considerable fluid with a urinous odor escaped. The superficial fascia was gangrenous. The prepuce and integument of the dorsum of the penis were divided, giving exit to more fluid. A No. 16 silver prostatic catheter was passed with ease, and ℥ x. of urine drawn off. Examination of the rectum showed two openings on the anterior wall, into which the finger could be passed. Prostate seemed normal. Very free incision was made in the median line of the perineum and scrotum; the urethra, for two inches anterior to the prostate, was opened; all the tissues beneath the deep layer of the perineal fascia were in a condition of gangrene; in half an hour patient had a severe

chill; temperature only 99½, and was free from pain. Patient took plenty of nourishment.

Dec. 23d.—Pulse, 130 per minute; temperature, 100°, respirations, 50; complains of dyspnœa. The gangrene has extended so that there is a spot about as large as the palm of the hand above the incision on the abdomen, which is perfectly dead. Diarrhœa commenced at 11 A.M., and he had eight passages up to 2 P.M., when it stopped. No vomiting; tongue dry, and coated brown; pulse feeble and rapid; sweating; headache; pupils contracted; no delirium; patient perfectly rational and conscious. Died in this condition at 8.15 P.M.

Autopsy was made twenty hours after death by Dr. W. H. Porter, Curator to the hospital. Around the incisions in the perineum the areolar tissue was gangrenous. The pericardial sac contained a drachm of straw-colored fluid. Heart weighed eleven ounces. Aortic and pulmonary valves slightly thickened. Atheromatous degeneration of aorta. Lungs œdematous, slightly adherent, and contained in their apices pigmented nodules the size of a hen's egg. Liver slightly enlarged and fatty. Brain-vessels of meninges distended. Dura mater adherent, arachnoid thickened.

The genito-urinary organs were removed *en masse*, and when dissected presented the following appearances:

The external incision in the perineum was four and one-half inches long. After removing the integument from the penis and adjacent parts, the areolar tissue was found gangrenous, the gangrene being most marked on the left side, extending down the spermatic cord nearly to the testicle. On the dorsum and left lateral portion of the penis there was a large patch of lymph, surrounded by gangrenous tissue.

The tunica vaginalis on both sides contained considerable clear, straw-colored serous fluid. The penis was laid open along the median line on the dorsal surface; the os pubis cut through, and the bladder opened on its anterior surface. The following conditions were found from meatus to kidney: The anterior three and three-fourth inches of the spongy portion of the urethra were normal. From this normal part to the prostatic portion the first inch was ulcerated and almost gangrenous. The balance of the urethra back to the prostatic portion had been entirely destroyed by the gangrene. The incision into the urethra was two inches long, and extended from the prostatic portion through the gangrenous part to the ulcerated portion. Prostatic portion of the urethra nearly normal; prostate normal. The bladder contained about four ounces of decomposed urine. On the mucous surface of the bladder there was some twenty bright red projecting points, which looked like loops of vessels. The ureters and pelvis of the kidneys were normal, but the latter were small and very white in color, although the vessels were well distended with blood. Microscopically, they were found in an advanced stage of chronic diffuse degeneration, and the tubes devoid of epithelium, and in many places filled with hyaline casts.

The rectum was opened on its posterior surface. In the first two and a half inches above the anal orifice six ulcerated points existed, which had fistulous openings running from them and terminating in blind extremities. There was no communication between these ulcers, and the bladder and urethra. One of these ulcerated points was quite extensive, and had destroyed all the coats of the rectum, and looked as if it might have formed as a small abscess in the coats of the rectum. Above this point the remaining portion of the rectum was more or less ulcerated and indurated, and the lumen considerably diminished at points. The point in the urethra where the extravasation of urine first occurred could not be determined, owing to the great destruction of the membranous and lower spongy portion of the urethra by the gangrenous process.

STRANGULATED FEMORAL HERNIA. REMOVAL OF SMALL PORTION OF OMENTUM.

A second specimen, presented by Dr. Briddon, consisted of a portion of omentum, removed in the operation for strangulated hernia. The patient, a female, aged thirty-three years, was admitted to the Presbyterian Hospital, December 31st, suffering from strangulated femoral hernia.

About one year ago patient fell from a sofa, and on the following morning noticed a lump just under Poupart's ligament, on the right side. It was very painful and tender to the touch. During several months patient suffered much from colicky pain in the abdomen, but had no vomiting. Bowels were regular. Began wearing a truss five months ago. According to her statement the hernia has been down from the first, never going back. December 30th the pain at seat of hernia became so severe that she consulted Dr. Briddon. She had vomited once December 28th; bowels constipated; complained of flatus. On admission, December 31st, one P.M., patient had no acute symptoms of strangulation, only the ones mentioned above. Three P.M., operation under ether and with all antiseptic precautions; an incision two inches long was made through the integument on the right side, the centre of which was about an inch outside the spine of the pubes. On dividing the cribriform fascia in the lower end of the wound, a rather free hemorrhage occurred from either the saphenous vein or one of its tributaries; this was checked at once by the application of a gut ligature. After this it was difficult to distinguish the different tunics, the fascia propria was thickened, as in most irreducible herniæ, or in those small protrusions that have long been covered with a truss, or it was so incorporated with the serous lining as to be almost inseparable. An attempt to reduce without opening the sac, by dividing such fibrous structures as appeared to prevent return, demonstrated that the stricture was in the neck of the sac itself, and that structure was divided, giving exit to one drachm and a half of clear, inodorless serum and displaying a small portion of omentum. Sac and contents were not larger than a small hickory-nut: the omentum was tied off with a strong catgut, and placed within the inner opening of the canal. The sac, which was separated from its investments, was also tied and cut off; a drainage tube was introduced; the wound was closed and protected with the usual antiseptic dressings. It is now fourteen days since the operation, the wound is nearly healed, and the patient has not had a bad symptom.

CARIES OF TARSUS—GOUGING FOLLOWED BY AMPUTATION THROUGH ANKLE.

Dr. Briddon presented a specimen of caries of tarsus, for which Symes's amputation had been performed. The following history of the case, by Dr. Wetmore, house-surgeon to the hospital, was presented:

Mary A. McGoff, æt. 34, married; housewife. Admitted to Presbyterian Hospital September 1st. Father died of cancer; mother died in childbirth;

has five sisters living and in good health, patient had had erysipelas. About one year ago last June she had pain in the right foot when walking; no history of injury. This increased until February, when she was unable to walk at all. In May four openings appeared, from which there was a free discharge of pus.

On admission, right foot very much swollen and red; four sinuses; deepest, one and a half inches, three on the inside; one on the outside. Bare bone could be felt; severe pain. September 11th an incision was made over the outer and inner surface of the foot, and portions of the internal cuneiform and cuboid found to be carious. All of this was removed with a gouge. Drainage tube passed through the wound, the tendo Achillis divided, and the foot put up in plaster. Wound afterward syringed with carbolic acid, 1-40. For a time patient did very well, and then more carious bone was found; temperature remained constantly up; swelling and tenderness around the wound increased, and the patient's general condition grew worse. A consultation was called for October 20th. Some recommended amputation; some injection with Villath's solution, which latter was done while the patient was under ether. This was continued for a month, at first seemingly doing good.

At the end of November it was evident that the disease was spreading and that the patient's general condition was growing worse every day.

Service of Dr. Briddon, December 1st.

Patient has a great deal of pain in the foot, which is swollen, tender, red, and hot. Her temperature is constantly above normal, 100 in the morning, 102–104° in the evening; diarrhœa, night-sweats, loss of appetite, cough, with slight dulness of apex of right lung, few crepitant râles, emaciation. Herpes zoster over back and nates.

5 Dec. 20th.—Symes's amputation was performed antiseptically by Dr. Briddon. The tuberosity of the os calcis, instead of being enucleated from below upward, was separated from above downward. The articular cartilage on the lower surface of tibia was covered with organized false membrane, which was scraped off and the cartilages found to be healthy. Dressings changed on second day.

Dec. 26th.—Everything looking well. Drainage-tube removed. Patient is in much better condition. Appetite improved, temperature lower, cough stopped, night-sweats less.

Examination of the diseased bones by Dr. J. Aycrigg Hegeman.

The foot was enlarged, thickened and œdematous. The thickening was especially marked over the articulation between the internal cuneiform and metatarsal bones of the great toe. Large sinuses, surrounded by exuberant granulations, leading down to bare bone, existed on both sides of the foot.

That on the inner side, as the dissection proved, led down to the articulation between the astragalus and scaphoid. That on the external side led down to the articulation between the cuboid and os calcis. The bones were cleaned by careful dissection and the following condition was found to obtain: The astragalus was normal, with the exception of the head, and the anterior facet on the inferior surface, on which the calcaneo-scaphoid ligament rests, both of which were carious and the former of which was entirely destroyed. The os calcis—the sustentaculum tali—was carious and presented a worm-eaten appearance. The facet for articulation with the cuboid was entirely destroyed by the carious process. The remainder of the bone appeared to be normal. All the articular facets of the scaphoid were entirely destroyed and at various points small osteophytes projected from the surface of the bone. Between the internal cuneiform and the first metatarsal bone, nature had stopped the carious process, by a firm bony anchylosis, large osteophytes growing from both bones, which in some instances united with each other. The other articular surfaces of the bone internal cuneiform—were roughened and destroyed. All the articular facets of the middle cuneiform were roughened and destroyed, the articular end of the second metatarsal bone being involved in the process. There seemed to be an attempt at anchylosis between the two bones. There were numerous osteophytes. The facet of the external cuneiform, for articulation with the third metatarsal, was normal, all the other articular surfaces were destroyed. The bone was covered with numerous osteophytes. The articulation between the cuboid and fourth and fifth metatarsal bones was normal, all the other articular surfaces of the cuboid were destroyed and the bone covered with osteophytes. The metatarsal bones were not involved in the process, with the exception, as stated above, of the first and second. The diseased bone was stripped of its periosteum, and presented a honeycombed appearance. It was brittle, easily broken, and looked dark and dirty.

Strumous Arthritis—Resection of Knee-Joint.

A fourth specimen by Dr. Briddon was one with strumous arthritis, resection of knee-joint.

Frank Ross, æt. 5, New York; admitted to Presbyterian Hospital, service of Dr. Briddon, July, 1878. Mother died of phthisis. Father living and healthy. The child had always been delicate. When admitted he had chronic arthritis. The joint was swollen, but there were no signs of acute inflammation. Child's general condition was very poor. Expectant treatment was tried until February, when the joint was aspirated by Dr. Post, and about eight ounces of fluid drawn. The joint was then hyper-distended with carbolic acid, 1-40. This treatment was followed by repeated blistering. In June, 1879, the knee was aspirated again. Then an incision was made just above the knee, and about four ounces cheesy pus were let out. No communication with the joint. After this there were signs of acute inflammation for three or four weeks, the child's temperature ranging as high as 104°; the knee was red, swollen, tender, and hot. In July, a brace was applied to immobilize the leg and to straighten it.

July 23d.—Several ounces of creamy pus, with some fibrinous clots, were removed from the vicinity of the knee by the hypodermic syringe, and afterward by a free incision. A drainage-tube was inserted, the old brace removed, and lint and bandage applied.

August 9th.—The cotton was removed to-day, as there was a foul odor. About four ounces of badly-smelling pus came away. The child seems to be failing in health.

August 16th.—A movable brace was applied. There is but little discharge of pus from the opening. General health is somewhat better.

August 29th.—Child very much improved. Appetite good and gaining in weight. Cotton and movable brace removed every few days and wound washed with acidi carbolici, 1-40.

September 15th.—Brace still on child's leg. The incisions are about healed. There is but little discharge.

September 30th.—Child's general condition is improving.

October 4th.—The brace was removed to-day and a new dressing applied. There was very little discharge and the sinus seems entirely healed.

October 11th.—He hobbles around on crutches and complains of no pain. The leg was straightened a little this morning.

October 15th.—Leg was dressed to-day. There was very little discharge.

October 25th.—He is quite restless at night, crying and moaning a great deal. Has pain in his head and head is drawn down toward left shoulder. No rise of temperature.

November 1st.—General condition a little better. He sleeps better. Given ol. morrhuæ.

November 20th.—Dressing changed to-day and brace reapplied. But little discharge.

December 2d.—A probe introduced through one of the sinuses on the inside of the knee passes into the joint and comes in contact with carious bone.

December 4th.—He complains of pain in the knee, especially at night. The head is drawn to the left side, and he lies in bed with his head buried in the pillow. Temperature 101¾ at night; normal in the morning. He cries continually in the night and refers the pain to the knee. Pressure of the head downward upon the spinal column increases the pain. Ordered potass. bromid., gr. v., every two hours during the night till he is quiet.

December 10th.—The pain in the head is better and the neck is not so stiff. Sleeps well. Very little discharge from the sinuses.

December 20th.—His general condition better than it has been for months. Given ferrum dialysatum ℥. x. t. i. d. with ʒ ij. ol. morrhuæ.

December 20th.—Examination of urine: sp. gr. 1016; color, light amber; sediment, white and flocculent, microscopically, lime oxalate, urate of soda; bladder epithelia and granular casts.

Operation.—December 27, 1879, by Dr. Briddon. Patient under the influence of ether, the spray, and associated antiseptic precautions. An incision was carried horizontally across the patella from the anterior border of the epicondyle on one side to the anterior border of the epicondyle on the other side. The joint was opened on either side of the patella; the bone was easily divided with the knife, and separated from its connections with the underlying articular facet of the femur. The lower half of the patella was then drawn downward and secured out of the way, while the lateral and crucial ligaments were divided, and the end of the femur resected. At this step of the operation, great care was taken to avoid removing more than a very thin slice of the epiphysis, and the section did not in any part approach or trench upon the junction of that process with the shaft. The head of the tibia was treated in the same manner, and by the removal of some thin additional sections, the bones were brought into accurate apposition, and maintained so by strong sutures of carbolized catgut (E violin string). The edges of the patella were then approximated, and also united by gut sutures. A drainage-tube was introduced through openings made behind the extremity of each lateral incision. The wound was closed with gut sutures and dressed antiseptically. The leg and thigh were covered with flannel rollers, and most thoroughly immobilized with lateral and posterior hoop-iron splints, maintained in position with plaster bandages covering foot, leg, and thigh, but leaving knee-joint open for inspection and dressing.

The child did not have a single bad symptom after the operation. On the following morning visit he was found sitting up in bed playing with his toys, as unconcernedly as if nothing had happened. The wound healed by first intention, and to-day, seventeen days after the operation, his general condition is very much improved. Condition of parts removed in operation: the cartilage on the internal condyle was carious, and the cancellous structure was in similar condition. Synovial membrane there was none; inter-articular cartilages gone, and the cavity replaced by fibrous tissue.

TWO CASES OF MELANO-SARCOMA OF THE CILIARY BODY AND CHOROID.

Dr. H. Knapp presented two specimens of intra-ocular sarcoma with the following remarks:

The first specimen was taken from a man, æt. 40, who consulted me on 4th August, 1879. He is an excellent painter, exceedingly industrious, and almost the only one in this city who paints on gold ground, which, he says, is very trying to the eye. He had worked a great deal at night by gaslight, and for two months he had seen, with his right eye, straight lines crooked. Further, he had suffered from photopsia and micropsia. On examination, I found extensive detachment of the retina. His other eye was healthy, emmetropic, and had perfect vision. Six weeks later he complained of fatigue, seeing colors and sparks and muscæ volitantes in the good eye. Though I could not find any abnormity, I treated him antiphlogistically for five weeks. The symptoms of irritation disappeared, and he resumed his work as before. In December, 1879, he came to me again, stating that his blind eye had given him great pain for two days. I found marked episcleral injection, chemosis, slight haziness of the cornea, discoloration of the iris, and the tension of the globe increased—in short, an attack of acute glaucoma. At once I examined the interior of the eye, and found in the lower outer part, immediately behind the lens, a brownish intumescence the size of a small pea. The diagnosis of a melano-sarcoma was at once evident. I may state here that from the beginning I looked for an intraocular tumor, but could detect no signs of it. The eye was free from irritation, and its tension rather diminished.

The globe was removed as soon as the diagnosis was made. A melano-sarcoma occupies the ciliary region and adjacent choroid. The retina is completely detached in shape of a funnel, but the other membranes are in position. The growth started from the ciliary region, and that was the reason that it was no sooner recognizable. It has the size of a hazel-nut, and must have had a considerable size when the retina became detached. Being at the periphery of the eye, it produced no great visual disturbance until the detachment of the retina took place. Microscopically, it presents a fine specimen of pigmented spindle-celled sarcoma.

The other specimen was taken from a healthy looking woman, æt. 30, who had been confined three weeks before she consulted me on Nov. 17, 1879. Two months previously she had accidentally noticed that her left eye was blind. When I saw her I found tortuous veins running over the sclerotic, the tension of the globe increased, the anterior chamber shallow, and slight perception only in the lower part of the visual field. The anterior outer lower part of the vitreous chamber was occupied by a brownish tumor. The retina was almost totally detached. The globe was removed. The tumor proved to be a melanotic spindle-celled sarcoma in the ciliary body and adjacent choroid, the size of a cherry.

Though it is very difficult to detect, at an early stage, neuralgias starting from the ciliary body, these cases, especially the first, very forcibly reminded me again of the necessity to carefully examine the hidden ciliary region in cases of ocular irritation, the cause of which is not seen with the ophthalmoscope, even when detachment of the retina has occurred.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 26, 1880.

DR. A. E. M. PURDY, PRESIDENT, IN THE CHAIR.

THE SOCIETY was called to order at 8 P.M. and the minutes of the previous stated meeting were read by the Assistant Secretary, DR. W. M. CARPENTER.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

The Comitia Minora reported, in relation to the matter of assessments by the State Medical Society for the publication of its Transactions, that, "after careful consideration, it finds no authority in the statutes for such taxation, and that the tax for publishing its Transactions is imposed illegally. That while it disclaims all sentiments of disloyalty to the State Society, it believes that the interests of the members of the Society of this county, and of the profession throughout the State, require that an earnest protest should be made against all assumptions of authority by the State Society that do not find their warrant in the statutes relating to the medical societies of this State."

The report was laid upon the table.

The Society granted Mr. Isaac F. Wood, the Librarian of the American Numismatic and Archæological Society, permission to have struck in bronze and white metal a few impressions of the County Society medal, for which he pays the die-sinker the cost, and to be placed in his own collection and in the cabinets of several societies.

The following clause relating to the Society's prize medal was adopted: "The Society reserves to itself the right to require that the essay for which a prize is awarded, shall be read before the Society previous to being placed at the disposal of its author."

The President was authorized, on recommendation of the Comitia Minora, to take such steps as are necessary to protect the interests of the practice of physic and surgery in the county of New York, the subject being before the Legislature in the form of a bill.

DELEGATES TO THE STATE MEDICAL SOCIETY.

On motion, the regular order of business was suspended, and the Society proceeded to the election of *five* delegates to the State Medical Society, to serve for the unexpired term of three years. The following gentlemen were elected: Drs. J. S. Warren, V. P. Gibney, A. McLane Hamilton, A. V. B. Lockrow, and Daniel Lewis.

PUERPERAL MALARIAL FEVER.

DR. FORDYCE BARKER then read a paper on the above subject, of which the following is an abstract: Although the title of the paper has not yet been added to the nomenclature of diseases in medical literature, it is so descriptivo of the etiology, pathology, and clinical phenomena of a class of affections which of late years had been so frequently met with in puerperal women in this city and its vicinity, that he had employed it. The author of the paper then presented the character of the disease, its pathology, its differential diagnosis, and its treatment. By the kindness of medical gentlemen who had furnished him with complete notes of cases which he had seen with them in consultation, and from those in his own private practice, he had the records of seventeen cases, and of these he gave a summary of the aggregate results and the conclusions to which he had arrived.

Puerperal malarial fever might make its invasion at any period following parturition, until the physiological changes which constitute puerperal convalescence were completed. The earliest development occurred in less than twenty-four hours after entirely normal parturition. The history of a case which occurred in the practice of Dr. Howard Pinkney was then given. The latest period of invasion was in one of his own patients, who had a normal labor in every respect, and her convalescence was so complete that he had begun to make weekly visits only. The details of the case were reported. The most prominent *symptoms* were chills, sometimes very slight, a temperature higher by one or two degrees, frequently, than was found in the beginning of any other puerperal disease, rapid pulse, greater prostration than was usual with other diseases during this period. After such an explosion, there was a remarkable remission on the following day, but the alarming symptoms returned after one, two, or three days, yet usually less severe. Only Typical cases, presented such a succession of phenomena. Dr. Barker was disposed to believe that in the majority of cases the patient, three or four days after the explosion, finds herself suffering a general sense of malaise, more or less of pain in the back, head, and bones, thirst, loss of appetite, insomnia; and when the disease was developed the chills were less severe, the pulse less rapid, the temperature not so high, and the remissions less marked; and he was also of the opinion that in such cases the disease was more persistent and responded less readily to treatment. In puerperal malarial fever a fall of temperature three or four degrees was always attended with a corresponding decline of other symptoms, which is not the fact in septicæmia, and the latter is rarely accompanied with pain in the head, back, and limbs. He thought that a competent and intelligent observer would not be likely to mistake the affection, when developed six or eight days after confinement, for pyæmia, even though it was developed late during the puerperal period. Puerperal fever usually appeared between the first and the third day after delivery, and very rarely after the fifth day, while the chills were not recurrent, nor were there marked remissions of the symptoms. Malarial fever may be developed during the progress of any of the local phlegmasia, or may be complicated by them. In five cases, secondary hemorrhage occurred after the twelfth day, apparently as the result of the malarial fever. One of these has already been reported by Dr. H. T. Hanks. In one case, three days after the hemorrhage, purpura was developed, and there was some oozing of blood from the nasal and buccal mucous membranes. In four of the cases seen in consultation the chief reason why he was called was that the patient was supposed to have puerperal mania. The details of a case seen in consultation with Dr. Barker, of Jamaica, L. I., were then given. But one of the seventeen cases had terminated fatally,

and that was in the practice of Dr. Wm. H. Hall. The patient died on the forty-seventh day after confinement. The history of the case was given. The author of the paper did not dwell upon the treatment, for the reason that the treatment of malarial fever is so well settled, and every physician of intelligence and sound practical sense appreciates the necessity for and the kind of auxiliary measures which the symptoms peculiar to each case may require. He had found Warburg's tincture much more effective and speedy in producing the results desired than the largest doses of quinia. His method was to give it in half-ounce doses every four hours until the fever had entirely abated, and then continuing it in gradually diminishing doses until convalescence is perfectly established. On the least threatening of a recurrence a full dose should at once be administered. The tolerance of quinia in these cases is very remarkable. One patient received 80 grains hypodermically within twenty-four hours, and yet no symptom of cinchonism was produced. When given by the mouth it is usually combined with bromide of potassium, to prevent or modify the cinchonism.

On motion, the paper was accepted, and being before the Society, Dr. Wm. H. Hall referred to a few points which the author of the paper had omitted to mention in the history of the case which he invited him to visit in consultation. The tolerance of quinia was most remarkable, no symptoms of cinchonism being produced while the patient was taking 150 grains in 24 hours. Another point in the treatment was the use of nitrite of amyl during the excessive prostration following the rigors. It perhaps did not cut short the chill, but the patient's powers of endurance seemed to be increased by it, and she was carried over the period of prostration much more satisfactorily than by any other means employed.

Dr. H. T. Hanks remarked, with regard to his case mentioned by Dr. Barker, that it was one in which he was much interested, because of some marked symptoms which appeared soon after delivery. At the time of delivery, the hemorrhage was considerably more copious than normal. After delivery her pulse remained at 95, and the doctor went away fearing the sudden occurrence of postpartum hemorrhage. She took full and repeated doses of quinine for five days, and at the end of the seventh day after confinement the temperature went down, and she did very well until the sixteenth day, when she was suddenly taken with uterine hemorrhage, which was profuse and carried her into an extreme exsanguinated condition. No cause for the hemorrhage could be found, and he could account for its occurrence only on the ground of the influence produced by a fever which could be subdued by no remedy except quinine. Dr. Hanks also referred to a case which he saw last June. The patient had lived in malarious districts south; had had well-marked malarial fever, and at the end of the fourth day after her confinement, labor being normal, secretion of milk good, lochial discharge proper, was taken with a chill. Large and frequent doses of quinine were at once resorted to, in combination with bromide of potassium. On the second day a second chill occurred, and on the fourth day a chill occurred, but it was much less severe than the first, the quinine was crowded, and her recovery was satisfactory.

Dr. S. S. Jones remarked that it had been his fortune to see a great deal of malarial fever in puerperal women within the last two or three years, and some of the cases had been exceedingly persistent and difficult to treat. There was one feature not noticed by the author of the paper, and that was the fact that septicæmia can occur after the onset of malarial fever in the puerperal condition, and that it may be the occasion of elevation of temperature without remission for several days, thus accounting for the fact that quinine does not produce its effect as quick as it usually does in pure malarial fever. It had been his habit to give, living as he did in a malarious district, a dose of quinine on the day following the confinement. In those cases in which fever does not subside after the exhibition of a full dose of quinine, it had been his habit to cleanse the uterine cavity, and in one or two cases he thought he had almost demonstrated that the cleansing of the uterine cavity was the turning-point in saving the patient's life. A case was related. Twenty grains of quinine were given after confinement, and ten grains daily until the sixth day. The patient was doing well, and the quinine was omitted. On the seventh day a violent chill came on, the temperature rose to 104° F., and in spite of large doses of quinine—45 grains in 12 hours—and thorough cinchonism, the fever and chills continued for three days. The cavity of the uterus was then cleansed by means of a probe and cotton, and the next morning, without the administration of quinine, the temperature was 103° F.; twelve hours afterward 102 F. The uterine cavity was cleansed three times, and the patient made a good recovery. The quinine was continued in the treatment, but not in very large quantity.

In a case of placenta prævia, the temperature, after delivery, rose to 104° F. It yielded to quinine, but the elevation returned, and symptoms of septicæmia followed. The case was treated by cleansing the uterine cavity, in addition to the use of quinine. The point to which he wished to direct especial attention was that when the elevation of temperature persisted in spite of the use of quinine, although there may be no tenderness of the abdomen, and many of the ordinary symptoms of septicæmia may be wanting, we should cleanse the uterine cavity, and not take it for granted that it is not a case of septicæmia.

Dr. Wm. T. Lusk remarked that he had not had any personal experience in cases corresponding to the severer form of malarial manifestation in puerperal women, described by Dr. Barker; yet ever since Dr. Barnes read his paper before the American Gynæcological Society, drawing attention to the fact that women living in a malarious region were subject to severe attacks of malarial fever immediately after confinement, his attention had been turned in that direction, and he had watched such cases with a great deal of interest. Within the last three months he had had three cases of the milder manifestations of malarial poisoning after confinement; chill, high fever, profuse perspiration, and all yielded readily to quinine. He regretted that post-mortem data had not been obtained regarding the severer forms. He thought that in some of the cases described by Dr. Barker septic symptoms were superadded, and aided in making them exceptionally severe. In the Maternity Hospital, when the report was made by the House Staff that some of the women had severe chills and high fever, followed by profuse perspiration, and that yielded readily to quinine, he always knew it was only the forerunner of something more serious, and therefore a warning. If the women were not removed, peritonitis and cellulitis began to appear in other cases; and if still the warning was not

he had, there came an outbreak of puerperal fever. He could not but think that, at the bottom of the severe cases at least, there was some other poison than malaria, differing only in intensity, perhaps in the manner in which it enters the system, rather than in the quality and character of the poison itself, and capable of producing puerperal fever. He thought we should be on the alert in making a distinction between this form of poison and that which produces true malarial puerperal fever.

Dr. Rankin suggested that it was not convenient to obtain post-mortem data unless patients die. Only one of the seventeen cases he had seen had terminated fatally, and in that one the question of septicæmia was thoroughly discussed by Dr Hall, Dr. Thomas, Dr Metcalf, and himself, and all were unanimous that there was not the slightest ground for suspecting septicæmia.

Dr. Hall thought the question of septicæmia was very pertinent, the object being to draw a nice distinction between it and puerperal malarial fever. With reference to his case, the prime object in calling the consultation was to see if he had not overlooked some complication, and all were of the opinion, as he had been, that it was one of malarial origin. The case had a distinct malarial history. The injections were all vaginal.

Dr. Jones further remarked that in one of his cases there was no tenderness of the abdomen upon pressure, the patient ate ordinary food with a good relish, the secretion of milk was not entirely suppressed; but when the soft catheter was introduced into the uterus, it gave exit by the injection to some badly-smelling discharge not previously noticed, and the cleansing of the uterine cavity was followed by a fall of temperature.

Dr. Charles Milne referred to cases similar in character to those reported, and in all there was a distinct history of previous suffering from malarial fever. He advised the prophylactic use of quinine in women living in malarious districts.

Dr. A. A. Smith mentioned that in several of Dr. Barker's cases there was history of malarial disease before confinement. He also stated that it was Dr. Barker's habit to put his patients upon the use of quinine immediately after confinement, and continue it for ten days, beginning early in January and continuing until the middle of June, but not at other times in the year, unless there was some special indication for its use.

Dr. W. R. Gillette remarked that he had recognized the presence of malaria in puerperal cases, especially in the upper parts of the city, and upon Blackwell's Island at the Maternity Hospital. In that institution almost all puerperal women were placed on the use of quinine and carbolic acid, at least when he was on duty, and it had come to be an established plan of treatment. To diagnosticate between puerperal malarial fever and puerperal fever is difficult in some cases, yet he believed the differential diagnosis could be made and mainly by the facies of the patient, the character of the chills, the absence of pain, the range of the temperature and the pulse, the purity of the lochial discharge, and by the purely functional disturbance of the gastro-intestinal tract, no constipation, and no great lack of appetite. Undoubtedly there were cases in which septicæmia was engrafted upon the puerperal malarial condition. He was glad that the subject had been brought up, for he believed that the profession does not recognize as it should the influence which malaria exerts upon puerperal women.

Dr. T. A. Emmet referred to cases in which there was uterine hæmorrhage, subinvolution, cellulitis, occurring in women who had been living in malarious districts, and which could not be cured except by the use of quinine. He very frequently found enlargement of the uterus, apparently due to nothing except engorgement from obstructed portal circulation; so he could well understand how a woman, exposed to malaria previous to her confinement, would be rendered susceptible to puerperal malarial fever.

The discussion being closed, Dr. David Webster, on behalf of Dr. C. R. Agnew, read the following memorial to

THE LATE DR. EDWIN DENISON MORGAN.

"Edwin Denison Morgan, Jr., a late member of our Society, was born in 1834 at Hartford, Connecticut, and died at Suffield, in the same State, on the fifteenth of August, 1879. His remains were buried in the family burial-place, in the Cedar Hill Cemetery, Hartford, on the eighteenth of August, 1879. His life was not what would be called a very eventful one, but it had one great quality, that it grew brighter and more beneficent as it advanced, until it ripened under the benign influence of Christian faith, and closed, leaving a priceless legacy to his family that there was a well-founded hope of blessed immortality.

"Dr. Morgan got his early education at Greenwich, Connecticut. At fifteen years of age he made a voyage around the world in a sailing ship. At its close he entered the Literary Institute at Suffield, Connecticut. At nineteen years of age he married Sarah E. Archer, of that town, to whom, under God, as he was wont to say, he owed a debt of gratitude impossible to overestimate.

"From 1850 to 1862 he served as colonel on the staff of his father, then Governor of the State of New York, and saw something of that political storm which burst upon our country in the great civil war; and the bold and fearless stand which his patriotic father took to cast the entire power of our State on the side of our menaced national unity.

"It was after that time that his life became a more earnest one, and to be inspired with motives of a character which impelled him to resist more actively the inducements to luxurious ease which abundant pecuniary means so constantly presented. He determined to devote the rest of his life to the arduous pursuits of our profession. He went to Europe in 1867, returned at the end of a year, and began the study of medicine at the age of thirty-three, with vigor, zeal, enthusiasm, and pertinacity, under the direction of Austin Flint, M.D. He graduated from the Bellevue Hospital Medical College in 1871. He soon opened an office on the west side of the city, near the quarters of the poor, and from that moment until broken down in health, in the spring of 1879, devoted himself, as the writer of this very well knows, to the unpaid care of the sick poor. I take back the word unpaid. He got his reward; for, although he, with exemplary reticence and meekness, tried to hide his beneficence from the gaze and applause of his fellow-men, it was seen, we must believe, by One who never allows a cup of cold water even to be given in true charity to a sufferer without a note in His book of remembrance against the day when earth and sea shall give up their dead for the final judgment.

"After many months of distressing, deepening, and weary weakness and waiting, he passed quietly away.

"A star will mark his name in our list *here*, and

let us fondly believe a Star will be added to the Crown of that Master in heaven through whose blood he trusted to be saved. It was a noble thing for him to enter the profession as he did at thirty-three years of age, and to struggle that he might do good to others. Let us not forget, then, that one crowning, closing episode in his life.

"No mere perfume of rhetoric can embalm a human memory. It must live or die in virtue of its own intrinsic vitality. As we turn away from the new grave of a departed friend and colleague, let us ask, every man ask himself, who next, and whither? —who next, and whither?"

Dr. J. W. S. Arnold presented a communication relating to vivisection, which obtained the support of the Society and the appointment of Dr. Arnold and Dr. John C. Dalton as a committee to oppose the bill against vivisection introduced into the Legislature through the influence of Mr. Henry Bergh.

The President announced that Dr. C. R. Agnew would read a paper at the Stated Meeting in February, and the Society then adjourned.

Correspondence.

SUITS FOR MALPRACTICE.

To the Editor of The Medical Record.

Sir:—The editorial in the Record of January 17th, in which you commend Dr. C. A. Robertson, of Albany, for having resisted to a successful termination a suit for malpractice which had been brought against him, was read by me with a great deal of interest.

The doctor pursued the right course. Had he cared to do so, the suit could probably have been settled for half what it cost him to defend it; and then, encouraged thereby, others in that vicinity who had received real or fancied injuries at the hands of some physician, as well as another class who saw a promising chance for speculation, would have resorted to the courts, hoping thus either to maintain the justness of their cause, or else extort for themselves a promising amount of hush-money.

Dr. Robertson will not, for some time, at least, be again troubled with a malpractice suit.

Having had a little instructive experience in one case, I can speak upon the subject with some considerable degree of assurance. The real reason for these suits lies often, but not always, at the door of some professional brother (?). Young lawyers, and sometimes older ones, are occasionally found who are extremely fond of publicity, little caring what brings it, and they, adding encouragements to the already half-formed purposes of their clients in these cases, eventually gain for themselves unenviable notoriety; and if the case is taken in hand by the lawyer with the understanding that he is to have the lion's share of the spoils—as is usually the bargain—then the only remedy for the physician who has been so unfortunate as to be attacked is to supply his own counsel with money and instructions to fight it out—never to compromise.

My experience, briefly related, was this:

About three years ago a seedy-looking and perfectly irresponsible young man applied to me to be operated upon and treated for a chronic blennorrhœa of the lachrymal sac and stricture of the naso-lachrymal duct.

I explained to him the nature of the disease and treatment required, but gave no *positive* assurance that a perfect cure could be effected. He set forth, in a way that wrought upon my sympathies, the many troubles and privations of his early manhood, and I undertook the case upon receiving from him a small fee—a mere trifle of what is usually paid for similar services.

As had been my practice in half a hundred such cases, I divided the lower punctum and canaliculus, afterward the stricture, dilated with Bowman's probes, and, with an Agnew's syringe, washed the parts with an astringent injection.

Having devoted most of my time during the past twelve years to the practice of a specialty here, I flatter myself that the treatment was skilfully and carefully applied. The improvement was marked and rapid, and at the end of three weeks there remained but little of the former difficulty, although further treatment was required. At this time my patient suddenly announced that he was going home or away to work, and, contrary to my advice, he left, but promised to return soon to have the treatment resumed. Ten months passed away and I had not heard or seen anything of him. Imagine my surprise on being one day served with a summons and complaint, setting forth great and irreparable damages to the complainant's eye, nervous system, general health, business, etc., by reason of ignorant, unskilful, dangerous, and severe—he should have added wickedly malicious—treatment and injuries received at the hands of the defendant, and demanding a salve for his injuries in the modest sum of five thousand dollars. To strengthen his case, positive perjury as to the amount paid me was recklessly thrown in, with half a score of other misstatements.

His lawyer was an ambitious young disciple of Blackstone, with a decided *penchant* for litigation, if not for something deserving of a *blacker* name.

The suit was defended, and my attorney urged it to trial as rapidly as the obstacles thrown in the way by the opposing counsel—and they were numerous—would admit of. After nearly two years' delay, the case was called for trial and dismissed, and shortly afterward the impecunious plaintiff was taken into custody by the sheriff, on a body execution, and he now lies languishing in the county jail, where he has ample time to reflect upon the uncertain results of an appeal to the blindfolded goddess for assistance in his schemes for evolving a large amount of wealth out of the purses of the disciples of Æsculapius. This was not his first attempt in that direction.

This suit could have been compromised for a small sum; but, believing it was a duty that I owed to myself and to the profession here to defend it, I did so.

The result, getting the plaintiff into jail, was a possible sequel to such cases that few who contemplate suing a physician for malpractice are cognizant of, and the lesson from the case has virtually ended another suit which was in progress here against another physician.

Having intelligently and with a reasonable degree of skill treated their patients, physicians can and *should* defend themselves against claims for malpractice, and not buy at any price immunity from what they may look upon as unenviable notoriety. It is not very flattering to your business or vanity to have it said that you were sued for malpractice; still we have rights and should defend them, not

quickly subject to having every one with more greed than honor levying tribute upon us. The judgments which physicians form in these cases are purely mercenary ones. No honest practitioner need fear them; they are never found.

Putting a few of the class of people who bring most of the malpractice suits into places of safe-keeping, unless they promptly pay the costs if they are defeated, would have a salutary effect, not only upon others of the same sort, but also upon the aspiring attorney, who, taking the case upon speculation, hopes to squeeze or worry the doctor into paying something handsome as the cheapest and easiest, if not most honorable, way of escaping from the clutches of the human vampire. There would be less trouble if the lawyers were obliged to change places with their clients at the end of the trial.

J. K. STOCKWELL, M.D.

OSWEGO, N. Y.

OPERATIONS FOR THE YOUNGER PRACTITIONERS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Having witnessed many surgical operations in the different institutions of this city, performed by members of the profession in the highest ranks, I am compelled to ask, through the columns of your valuable paper, why these gentlemen are not as willing to afford the younger members an opportunity to operate as they were to teach us in our student days. Some of our highly esteemed professors will watch their chance to perform the smallest and simplest operation with the utmost jealousy, while we younger practitioners, to whom they have granted diplomas, must take a back seat. Many of our patients avail themselves of the services of these men simply because of their high standing and their willingness to operate for glory, and not for fees, and we are thereby deprived of a very important and remunerative portion of our practice.

The dispensary system has long been cried against, but is this not also a matter which merits a little attention in behalf of the young practitioner?

With all due respect to these veterans, who have grown gray in practice, and who have already an established reputation, I would suggest that, while they attend to the larger operations, they give us an opportunity to perform some of the minor ones; such, for instance, as strapping an ulcer or opening an abscess.

Very truly yours,

DE PROFUNDIS.

NEW YORK, January 21, 1880.

A CASE OF SUDDEN DEATH FROM THORACENTESIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—As I see by the late journals that discussion is still kept up on this subject, the following case may not be without interest:

The patient, a young man, aged twenty-five years, was admitted into the hospital on the evening of November 10th.

I found him, on my visit next morning, sitting up in bed, and breathing with great difficulty from compression of both lungs by an enormous amount of fluid in the pleural cavities (cause, acute desquamative nephritis). The urgency of the symptoms appearing to demand immediate relief, I decided on thoracentesis.

Not forgetting the danger of a too rapid evacuation of the pleuritic fluid, I selected for the purpose the smallest needle accompanying an ordinary aspirator. Hardly had twelve ounces been drawn, however, before he complained of being faint. I immediately closed the discharge-cock, and was about to put the patient in the horizontal position, when I bethought myself that suffocation was imminent even while sitting upright. This action then appeared contraindicated, and resuscitation was attempted by the usual means, including hypodermic injections of brandy and ether, by electricity, etc., but all to no purpose; he never "came to." He had complained of no great pain from the operation. I am of the opinion that the immediate cause of death was syncope.

D. B. SIMMONS, M.D.,

Surgeon to Kerr Hospital, Tokio, Japan.

JAN. 2, 1880.

[It must be recollected that our correspondent lives in Japan, which accounts for his letter appearing a little late. But we shall always be glad to hear from him at any time.—ED.]

THE CHORDA TYMPANI NERVE.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—It is a source of very great gratification to me that my observations upon the chorda tympani nerve have been confirmed in their most important part, by so conscientious and thorough an investigator as Dr. Spitzka. It was not without hesitancy that I published my conclusions, for I felt that I stood alone in a field which had been traversed in opposite directions by leading physiologists. I am greatly obliged to Dr. Spitzka for his little note, and since the facts upon which true science rests have been evolved from the most divergent opinions, I shall enter with pleasure upon a further investigation of the sensory function of the chorda tympani. The investigations of Dr. Spitzka have covered a larger field than my own, extending over a larger period of time, and I naturally give to any opinion of his a great measure of weight, especially as I am unable to prove *absolutely* the sensory function of the ganglion upon the nerve. It may act simply as a storehouse.

Respectfully,

HORATIO R. BIGELOW, M.D.

1502 14TH STREET, WASHINGTON, D. C.

MONUMENT TO GALVANI.—The marble monument erected by the Bolognese to the memory of their celebrated fellow-townsman, Luigi Galvani, the physiologist and discoverer of galvanism, was unveiled with imposing ceremonies. The monument is the work of a young sculptor named Adalbert Cencetti; it represents the savant clad in the costume of the last century, standing and watching the movements of the muscles of a frog on an apparatus placed on a table beside him. The monument stands in the old Frie lensphatz, which has been rebaptized "Galvani Place."

HEALTH DEPARTMENT OF PLATTSBURG.—The city of Plattsburg has shown commendable enterprise by creating a board of health. Its statement of mortality for 1879 is before us. The rate of mortality for 1878 was 25 per 1,000; that for 1879 is only 19.22 per 1,000. This improvement can, doubtless, be laid in part or whole to the increased attention to sanitary measures.

ARMY AND NAVY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 25 to January 31, 1880.

HEGER, A., Major and Surgeon. So much of the order as directs him to proceed to San Antonio, Tex., on or before February 1, 1880, is amended to read on or before February 20, 1880. S. O. 19, A. G. O., January 26, 1880.

WHITE, C. B., Major and Surgeon. His leave of absence on surgeon's certificate of disability granted him July 24, 1879, extended six months on surgeon's certificate of disability. S. O. 20, A. G. O., January 27, 1880.

TREMAINE, W. S., Capt. and Assist. Surgeon. His extension of leave of absence on surgeon's certificate of disability of November 11, 1879, further extended twelve months on account of sickness, with permission to go beyond sea. S. O. 18, A. G. O., January 24, 1880.

Changes in the Medical Corps of the Navy during the week ending Jan. 31, 1880.

Passed Asst. Surgeon P. FITZSIMMONS, from the Naval Hospital, Yokohama, Japan, and to return home and await orders.

Passed Asst. Surgeon J. R. WAGGENER, detailed from the receiving ship at Boston, and ordered to the U. S. S. Vandalia.

Asst. Surgeon GEO. ARTHUR, detached from the U. S. S. Vandalia, and ordered to Naval Hospital, Norfolk, Va.

Asst. Surgeon S. H. DICKSON, detached from the Naval Hospital, Norfolk, and awaiting orders.

ERYSIPELAS IN BELLEVUE HOSPITAL.—Owing to the burning of the wooden pavilion in the Bellevue Hospital yard recently, it has been difficult to dispose of occasional cases of erysipelas arising in the wards. This has led to some exaggerated charges in regard to the presence of that disease in the hospital.

ST. MICHAEL'S HOSPITAL AT NEWARK—A new visiting staff has been appointed in place of the old one which resigned. Much indignation is expressed about the course of the managers, and there is talk of establishing a new hospital. Considerable money has already been promised for such a purpose.

A NEW EYE AND EAR INFIRMARY.—A number of prominent citizens of Newark have subscribed money for the establishment of an Eye and Ear Infirmary in that city. The institution is likely to be in running order before a great while.

EXAMINATIONS FOR ADMISSION TO THE U. S. MARINE HOSPITAL SERVICE.—Examinations for admission to the Marine Hospital Service have just been held at Washington. There were thirty-five applicants and two vacancies. The Examining Board consisted of Surgeons P. H. Bailhache, of the National Board of Health, C. S. D. Fessenden, now in charge of the Marine Hospital in New York City, and T. W. Miller, of Chicago. The examinations were mostly written, and lasted five days. Professor John Guiteras, of Philadelphia, was one of the applicants for admission.

YELLOW FEVER IN BRAZIL.—Yellow fever has appeared at a number of places in Brazil, notably Rio Janeiro. Not many cases as yet are reported.

A NEW HOSPITAL FOR THE INSANE.—As the result of the efforts of certain Catholic sisters, a small retreat for the insane has been established near Rye Point, in this State. It is called St. Vincent's Retreat. The location is said to be salubrious, and the arrangements for the care of patients excellent. Sister Mary Frances Wallace, formerly of the Half-Orphan Asylum of this city, is in charge of the institution.

THE EFFECTS OF CHLORAL ON EYES.—Dr. Wm. Badger, of Flushing, N. Y., writes: "In response to the inquiry from one of your correspondents as to the effect of chloral upon the eyes, I beg leave to state that I once had a lady object to my prescribing the drug, because, as she stated, it always affected her eyes so unpleasantly, describing the same symptoms mentioned by your correspondent."

DR. PAUL F. MUNDÉ has accepted an invitation to deliver the regular course of lectures on Gynæcology at Dartmouth Medical College during the coming fall.

THE LATE DR. FREEMAN J. BUMSTEAD, OF NEW YORK.—At a meeting of the New York Medical and Surgical Society, held January 10, 1880, the following resolutions in relation to the decease of Dr. Freeman J. Bumstead were submitted by a committee composed of Drs. Abram Du Bois and Fessenden N. Otis, and were entered upon the minutes of the Society:

"*Be it resolved*, That this Society has learned with profound sorrow of the loss, through death, of one of its most valued members, the late Dr. Freeman J. Bumstead.

"*Resolved*, That the present occasion is a most fitting one on which to express our appreciation of the honorable character and high professional attainments of our late associate, and our grief at his untimely death.

"*Resolved*, That in his industry, his untiring energy, his methodical devotion to the interests of medical science, and in his most valuable and extensive contributions to medical literature, we recognize a life worthy of all honor, and of being held in perpetual remembrance.

"*Resolved*, That while thus expressing our high estimation of his professional work and life, we do not fail to appreciate the rare talents and accomplishments of our late professional brother in other fields of scholarly pursuit, and that these, joined to a uniform unobtrusiveness of manner, a genial and friendly

tor are, had declared him to us, both as a companion and as a friend.

"*And be it further resolved*, That these expressions of our estimation of the life and character of our late beloved associate, and our sorrow for his loss, be transmitted to his family, and also be forwarded to the leading medical journals for publication.

"W. W. JONES, President.

"A. R. BALL, Secretary."

DEATH OF AN OLD PHYSICIAN.—Dr. Joseph W. Taylor, who died at Burlington, N. J., January 18th, was well known in Philadelphia. He was born in 1810, and, after graduating at the University of Pennsylvania, engaged for some years in mercantile pursuits in Cincinnati. He was also for a time a surgeon on a ship in the trade between Philadelphia and Calcutta. About twenty years ago he settled in Burlington, and during the later years of his life was much interested in the success of a college for the higher education of girls, now being erected in Delaware County, Pa. He was a member of the Society of Friends, as his ancestors had been for several generations.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY held its annual meeting on Wednesday evening, January 21st, for the election of officers for the ensuing year. Sixty-six members were present. Reports from the Board of Censors and Auditing Committee for Treasurer's accounts were presented and read by Dr. S. F. Baldwin. Reports were also received from the Treasurer, Recording Secretary, Corresponding Secretary, Assistant Recording Secretary, and Reporting Secretary. The Committee on Microscopy and the Publication Committee also presented reports for the past year. The following gentlemen were elected for the respective offices for 1880: Albert H. Smith, M.D., President; John H. Packard, M.D., Vice-President; H. Lennox Hodge, M.D., Vice-President; J. G. Stetter, M.D., Censor; Wm. M. Welch, M.D., Treasurer; Charles B. Nancrede, M.D., Recording Secretary; J. D. Nash, M.D., Assistant Recording Secretary; William Goodell, M.D., Corresponding Secretary; Frank Woodbury, M.D., Reporting Secretary; M. O'Hara, M.D., Librarian. Drs. Henry H. Smith, Richard J. Dunglison, and J. Howard Taylor, were elected delegates to the Convention to Revise the National Pharmacopœia, to be held in Washington, in 1880.

A ONE-EYED MONSTER.—In the Wood Museum, at Bellevue Hospital College, is the head of a mulatto baby, which shows a very remarkable peculiarity of development. The head is of the size usual in an infant, and is covered with short, woolly hair to about the normal extent. In the centre of the forehead is a large and well-developed eye. This bulges out almost as in an exophthalmic condition; it is not set in an orbital fossa, nor surmounted by an eyebrow. Below the eye is a depression, at the bottom of which may be seen two rudimentary orifices. These may represent the nose. Just below this is a small, fleshy tongue, about two-thirds of an inch long and half the thickness of a lead-pencil. Below, and on either side of this, are two ears. They are quite well developed and are placed nearly horizontal, so that their concavities look upward and slightly inward. The lobes nearly touch each other. There are no other peculiar marks or rudimentary features. The monster is evidently a single one, and its deformities are very peculiar. It seems, from a superficial examination, as though the whole central part of the face, from the top of the nose to the lower jaw, had failed to develop. The tissues uniting in front would thus bring the ears around into their present position. It is difficult, however, without a dissection, to account for the single eye and its peculiar position. The body of the infant has been lost. The monster was born in New Orleans. It was purchased by a physician, and forwarded by him to New York. The captain of the vessel to whom it was entrusted injudiciously showed the curiosity to the sailors. Their superstitions were excited, and the captain was obliged to pacify his crew by pretending to throw the body overboard. He first cut off the head, however, and only the trunk was lost. It came to the care of Dr. Jas. B. Chilton, of New York, and was given by him to Professor Doremus, who presented it to the Wood Museum.

A NEW REGISTRAR-GENERAL.—The position of Registrar-General of England, lately filled by Major Graham, is said to have been offered to Sir Brydges Henniker, Bart. The appointment is a political one, the new officer having no claim, on account of past services or special ability, to the place. Dr. Wm. Farr, who has been for many years Superintendent of the Statistical Department, was a candidate for the Registrarship. His well-deserved claim not having been recognized, he has sent in his resignation.

SLOW PULSE.—Dr. C. K. Kelley, of Milford, N. H., writes: "In your issue of January 10th some cases of slow pulse are noted. It reminds me of a case I had a few years ago—a young man sick (excessingly so) with acute dysentery. From beginning to the end of his sickness I never found his pulse exceeding *forty per minute*. He recovered in due time, and several months after, meeting him coming from his work (that of a carpenter), I asked to examine his pulse, as he was in fine health, when, lo and behold, it beat exactly the forty per minute as when he was suffering from the dysentery—no more, no less. I think such cases are rare, having never met one like it before nor since, where the frequency of the pulse was the same in severe disease and in good health."

DR. JAMES W. SCRIBNER, one of the oldest and best known physicians in Westchester county, died at his residence in Tarrytown Jan. 25th, in the sixtieth year of his age. He had for some years been the visiting physician at the county poorhouse.

LECTURES ON THE INFECTIVE PROCESS.—Dr. Greenfield has been appointed Professor Superintendent of the Brown Institute, in place of Dr. Burdon Sanderson. Dr. Greenfield will deliver a series of lectures on the infective process. It will embody the results of the experiments and studies at the Brown Institute during the past year.

ANOTHER DEATH FROM CHLOROFORM occurred at a surgical clinic in the Royal Infirmary, Liverpool, during the removal of a small piece of bone. The patient, a man, had taken the anæsthetic before with no bad symptoms. He had also taken ether, but so badly that chloroform was resorted to in the present instance.—*Brit. Med. Journal.*

THE BILL FOR THE CREATION OF STATE COMMISSIONERS IN LUNACY.—A bill was introduced into the Assembly by Speaker Sharpe, February 2d, providing for State Commissioners in Lunacy. It enlarges the present State Board of Charities by three members, whose duties are to examine into and supervise the lunatic asylums of the State. Two of the three new Commissioners must be physicians. The bill was prepared by the committee appointed at the Cooper Union meeting.

Original Lectures.

THE TREATMENT OF CANCEROUS ULCERS, AND GROWTHS NOT REMOVABLE BY THE KNIFE.

By STEPHEN SMITH, A.M., M.D.,

PROF. ORTHOPÆDIC SURGERY, UNIVERSITY MEDICAL COLLEGE; SURGEON TO BELLEVUE HOSPITAL, N. Y.

THE subject of this lecture will be :

The Treatment of Cancerous and Cancroid Ulcers, and Growths not adapted for Removal by the Knife.

You will frequently be at a loss to decide as to the course of treatment to pursue in cases like the one before you. In fact, such cases are usually regarded as not amenable to any treatment, and are allowed to progress, from bad to worse, until they terminate fatally. The results of such treatment are great personal discomfort, pain, and misery, and a lingering death. That such cases may often be greatly benefited by treatment there can be no doubt.

This patient is suffering from a return of cancerous masses in the margins of the old cicatrix, which formed after the removal of a cancerous tumor from the breast, one year ago. Nodular masses appear at several points, while, at the upper angle of the scar, the surface is extensively ulcerated. Her general health is very good, and as yet there is no evidence that cancer has affected internal organs. It may, therefore, be considered a local disease, so far as we discuss methods of treatment.

In the first place, it is evident that this is not a case for removal with the knife. It might be possible to dissect out quite clearly the hard masses, but the ulcerated portion has a base firmly adherent to the deeper structures. An attempt to remove all the tissues involved at this point would be very dangerous, and hence would be an unjustifiable procedure. Shall the case, then, be left to the natural results of the reproductive and destructive process now in progress? I think not. Though we may not hope to cure, we may mitigate and relieve symptoms, and possibly retard the progress of the disease, at least so far as its local manifestations are concerned.

The treatment which I propose to pursue is the application of a caustic. This remedy, though all but discarded by surgeons in the treatment of cancer, has a place in the therapeutics of malignant diseases not yet accurately defined. It is one of the destructive measures which we may resort to, having capacities limited only by the possibilities of its application. As ordinarily employed, its real virtues are not fairly nor adequately tested. We are advised, or rather permitted, by authorities to apply caustics to ulcerated cancerous surfaces, the growth being no longer amenable to the knife. That is, caustics are recommended, as a last resort, when the disease has taken such deep root that it is certain to prove fatal. If useful under such unfavorable circumstances, may they not be far more serviceable at an earlier period? In my experience, caustics judiciously selected, and thoroughly and persistently applied, give the best results of any method of treatment yet adopted.

But, instead of entering into a discussion of the general use of caustics in cancer, I shall limit my remarks to their application in the class of cases represented by this patient—viz., open or ulcerating cancerous growths not removable by the knife. The caustic which I shall select for this case is the anhydrous sulphate of zinc, which is the ordinary sulphate of zinc deprived of its water of crystallization by heat, and reduced to a fine powder. It may be used in the form of a powder sprinkled over the surface, or as a paste made with glycerine, or as a strong ointment. In any of these forms it is the most useful caustic which we have for open surfaces, and it is for the purpose of illustrating its uses that I have brought this case before you.

The employment of sulphate of zinc as a caustic first came to my knowledge through a publication of the late Prof. Simpson, of Edinburgh. At the time I read his article a case was in my ward at this hospital, which was well adapted to test its special virtues. The history of that case, and one or two others in which this caustic was used, will illustrate the methods of employing it, and the results which follow.

Before I detail those cases, I will apply the caustic to these cancerous formations, and notice some points made by Prof. Simpson. The forms that I may use are as follows: on the open surface I may apply the powder simply, or it may be made into a paste with glycerine, one ounce of the dried powder being used to one drachm of glycerine; or a caustic ointment may be formed with an ounce of the dried sulphate to two drachms of the axunge. Either of these preparations are useful on open surfaces. I have selected the powder because I found that it was the only one of these preparations ready for use. In dusting the powder over the surface, it should be so thickly applied as to cover the exposed tissues to the depth of an eighth of an inch or more. That it is not a painless caustic is evident from the complaints of the patient, but it is by no means as painful as many other caustics in popular use. The pain continues but a short time generally, and patients rarely hesitate about a reapplication. There is but slight tendency, as you see, in the caustic to spread, and I readily control it by absorbing the surplus with cotton. After the caustic has been on the wound three or four hours, any liquid residue should be removed by a swab of cotton, and a hot poultice applied. It will require five or six days to separate and detach the slough. It is a feature of the action of this caustic that the slough is, for the most part, white, and is not offensive. If any diseased tissue remain at the bottom of the wound after the slough is completely removed, reapply the caustic as before; but if a healthy surface remains, apply a simple dressing, as balsam Peru.

It will occur to you that it may be as dangerous to reapply the caustic to the base of an ulcer situated over important parts as to attempt removal by dissection. But that is not true, especially when you are employing a caustic which may be applied so lightly as the powdered sulphate of zinc. By very lightly sprinkling the fine powder, the thinnest possible slough may be removed. An additional safeguard is found in the local inflammatory action established by the caustic, which tends to protect underlying parts from injury.

In treating the hardened masses or nodules, we must not apply the powder itself, nor as made into an ointment or paste. For, though it may in these forms irritate the skin, it will not break the surface; that is, it will not act as a caustic where the epithelium is entire. This peculiarity, says Prof. Simpson, "is at once an advantage and a disadvantage: an advantage in so far as it prevents all fear of the caustic ever unnecessarily affecting any of the healthy

contiguous surfaces and parts, and renders its application and use far more simple and certain, and a disadvantage, because, when we wish to apply it to a non ulcerated structure, we must first remove the intervening epithelium by a small blister, or more effectually by the application of an alkaline or acid caustic." I have frequently experienced the advantages to which Prof. S. alludes, but never the disadvantages, because I find in another composition of the caustic an agent capable of destroying the skin. If the dried sulphate of zinc powder is mixed to a paste with the strong sulphuric acid, a caustic is produced of the greatest energy, and yet having all the good qualities of the other forms of the sulphate of zinc caustics. This preparation is an inert-appearing mass, resembling the plaster used by the masons, and will keep any desired length of time. For the reasons given, I select this caustic with which to treat the cancerous growths still covered with the integument. It is best applied with a stick or glass rod. In order to prevent pain, I will first apply the strong carbolic acid to the tumors as an anæsthetic. The surface immediately becomes white; serum is next effused, raising a distinct wheal, and now the local anæsthesia is complete. I will apply the caustic with this pointed stick, though a small glass rod would be better. Dipping the end into the caustic, I make a series of lines, and cross them at short intervals, rubbing the caustic into the furrows until the whole thickness of the skin is charred along the furrows. This operation, you see, is comparatively painless. A poultice must now be applied, as in the former case, and in about a week the skin will separate. On the reapplication of the caustic the powder may be preferable to this form, owing to the necessity of penetrating to a slight depth.

In regard to the action of the caustic, I cannot do better than to summarize Prof. S.'s publication. He states that the part to which it is applied is rapidly destroyed to a depth corresponding to the thickness of the superimposed layer; the slough is of a white color, and separates usually on the fifth or sixth day, leaving behind it, when the whole morbid tissue is removed, a red, granulating, healthy, and rapidly cicatrizing wound. This slough shows no tendency to chemical or putrefactive decomposition, but is firm in texture, and free from taint or odor; the local inflammatory reaction around a sulphate of zinc eschar is generally light and transient; there is no marked effusion or swelling in the surrounding parts, except where the caustic was used in the neighborhood of loose cellular tissue; the general system is not affected by its absorption, nor are there any constitutional symptoms, however freely and lavishly it is used.

It must be apparent to you that we have, in the sulphate of zinc, a caustic which, in its various forms, is adapted to a great variety of conditions. Prof. Simpson sums up its advantages, as compared with other caustics, as follows: "1. Its powerful escharotic action; 2. The rapidity of its action; 3. Its great simplicity and manageableness; 4. Its facility of application; 5. Its non-tendency to deliquesce or spread; 6. Its perfect safety; 7. Its efficacy." He speaks hesitatingly as to the seventh statement, but adds that he has seen not only the surface of cancroid and cancerous ulcers speedily and perfectly excavated by its application, but the surrounding characteristic induration become at the same time rapidly absorbed, and the remaining wound very speedily cicatrizes. He has also found epithelial or cancroid ulcer of the cervix uteri, under the local application of powdered sulphate of zinc, exfoliate its ulcerated surface, have its sanguineous and seropurulent discharges arrested, the parts temporarily, if not permanently, healed, and the patient's health, and strength, and spirits restored, though, on first using the caustic, he believed the disease to be altogether beyond the reach of any remedial measure.

My experience in the use of the sulphate of zinc as caustic has been considerable, and fully coincides with that given above. I will conclude by relating two cases, out of a record of a large number, which confirm Prof. Simpson's apparently exaggerated statements.

The first case was an old lady, 72 years of age, who entered the wards suffering from cancer of the right breast. She was extremely emaciated, and apparently in the last stage of exhaustion. The cancerous growth was of large size, and its surface was in a sloughy and offensive condition. Above the clavicle of the same side was another growth of the size of a small orange, quite movable and painless. At the consultation it was advised to make such applications to the breast as would destroy the offensiveness of the putrefactive discharges, give tonics, and leave the case to terminate fatally by exhaustion. The application selected was the sulphate of zinc, rendered anhydrous by heat, reduced to a powder, and then mixed with the strong sulphuric acid. This mixture formed a white paste, which was apparently inert, though it really had powerful caustic properties. The first application charred the mass to the depth of one-third of an inch. It was attended with considerable pain for an hour. A hot poultice was next applied for three or four days, when the slough separated. The application was then made a second time, and in due time the slough separated. Five repetitions completely removed the diseased mass, and exposed the muscles of the thorax. Simple dressings were then applied; the surface granulated well, and the cavity closed as a healthy wound. The cicatrix was soft and unadherent to the deeper tissues. She left the hospital much improved in health. Four years afterward she returned to the hospital, suffering from rheumatism, and my attention was called to her accidentally by an allusion to the fact that I had previously treated her for a tumor of the breast. It seems that she had led the life of a vagrant, being part of the time in the alms-house, and the remainder she spent wandering about the streets. There was but little change in her general condition. The cicatrix of the removed breast was soft and yielding, but firmly united as when I saw it last; the other tumor had opened, and presented a fungating red surface. She soon left the hospital, and was never examined again.

A case of uterine cancer soon after came under my observation. The patient lived in Jersey City, and at the time of my first visit was pale and emaciated, and had been confined to her bed for three months. She suffered from a constant discharge of thin, often dark, and always offensive matters, and had frequent hemorrhages. On examination, the neck of the uterus was found to have disappeared, and, with a speculum the interior of the uterus was fully exposed. The opening of the cavity was surrounded with a dense, nodulated ring of cancerous structure, from which depended shreds of dead tissue. The case was, of course, hopeless, so far as it might be possible to entirely destroy the cancerous degeneration, but there might be hope of arresting its progress, or of mitigating the most serious symptoms, viz.: hemorrhage. I accordingly applied a

thin layer of the caustic to the most prominent surfaces, and filled the cavity with cotton. On the following day the cotton was removed, and the surface was found covered with a light slough, which separated in three or four days, leaving a very healthy-looking base. The caustic was cautiously applied to different parts, from time to time, until at length the whole diseased surface was treated and a slough had formed and separated. The result was most gratifying; the hemorrhage did not recur; granulations sprang up freely, and appeared to be healthy; the discharge lost its fetor; she rapidly gained strength, and was soon able to leave her bed and take exercise in the open air. The last time I saw her, three months from the time the first application was made, most of the surface was healed. There were still hard masses, perceptible to the touch, but beyond the reach of the caustic; her general health was good, and she was attending regularly to all her domestic affairs. I learned, a year later, that she died suddenly of an uterine hemorrhage, doubtless from the destruction of an artery.

Original Communications.

PERFORATION OF THE SMALL INTESTINES.

By A. W. HAGENBACH, M.D.,
ASST. MED. SUPERINTENDENT COOK CO. INSANE HOSPITAL, JEFFERSON, ILL.

Perforation of the small intestines, excepting as a result of a penetrating wound, ulcerations accompanying typhoid fever, or some severe crushing injury, being a comparatively rare occurrence, shall be my excuse for reporting the two following cases which have come under my notice in the Cook Co. Hospital for the Insane.

Case I.—August L——, aged 60 years, was admitted July 18, 1878, and entered as a case of "mania." Upon examination after admission, found him fairly nourished, heart and lung sounds normal, with a history of excesses extending over several years. He made a rapid recovery, and was nearly well enough to be discharged, when, on the evening of November 5th, he sustained a fall while walking along a newly oiled hall floor. He was unable to get up unassisted, complained of severe abdominal pain, with feeble pulse, cold extremities, and all the symptoms of severe nervous shock well marked. Sinking rapidly, he died at 7.30 P.M., November 7th, just forty-eight hours after the accident. He vomited immediately after the fall, and very frequently afterwards, until within a few minutes of his death, vomiting stercoraceous matter during the night of the 6th and the following day. An injury to the abdominal viscera was diagnosed, but as the fall was a slight one, the resident medical staff were inclined to the belief that the injury resulted in an "internal strangulated hernia," which might have accounted for all the alarming symptoms present. The remedies employed were opium, to relieve pain and arrest the vermicular movement of the bowels; also brandy and punches as stimulants. A post-mortem examination was held fourteen hours after death. The peritoneal cavity was found distended with blood, serum, and the contents of the bowels. A large rent, almost severing the gut, was found in that part of the small intestines resting in the left lumbar region. Extensive adhesions between the intestines and internal abdominal ring were lacerated and probably the source of the hemorrhage. The serum was a result of the peritoneal inflammation, caused by the presence of the intestinal contents. Mr. L. had a large, oblique inguinal hernia, and frequently had trouble in reducing the contents. The adhesive inflammation probably followed the rough handling of the parts during his unskilled efforts at returning the contents of the sac. The case is mainly interesting from the fact that so slight an accident should be the cause of a laceration of the intestine and death.

Case II.—John D——, aged 62 years, was admitted July 17, 1869, suffering with "recurrent mania." In the intervals between the maniacal attacks he was allowed complete liberty to go and come as he pleased, provided he returned in time to lock up the patients, usually about 8 P.M. On November 25, 1879, he went to the village of Jefferson, about two miles distant, and indulged in several drinks (about ℥ vj.) of whiskey, and was returned to the asylum by an attendant about 6 P.M. He at once went to bed, complaining of severe diffused abdominal pains, pulse 80, and slightly feverish. Regarding the symptoms as due to the debauch and exposure, prescribed mustard-plaster to abdomen and carminatives internally. Next morning he expressed himself relieved of the abdominal pain, but instead complained of a shortness of breath and pain in the chest. Upon physical examination, found the signs of pleuro-pneumonia of the lower lobe of the right lung and adjacent pleura well marked. As his bowels had not moved for forty-eight hours, prescribed ℥ i. castor oil, to be taken at once; muriate of ammonia mixture, ℥ iv., teaspoonful at a dose every three hours; and gr. ¼ sulphate of morphine as frequently as indicated after the bowels had moved. During the afternoon the abdominal pain returned, greatly intensified, pulse 110, and respirations 30 per minute. The temperature, unfortunately, was not taken. At 9 P.M. the pain was excruciating, pulse quick and small, respiration hurried.

Thinking that a free movement of the bowels might afford some relief, administered an enema of about a gallon of luke-warm water, first examining the chest and finding the pneumonia involving nearly the whole of the right lung. After the enema, his bowels failing to move, he lay on his abdomen, and after a few convulsive movements expired without a groan. So sudden a death could not be accounted for by the pleuro-pneumonia. The bright red color of the lips showed that the blood as yet was fairly oxigenated. A post-mortem, held eleven hours after death, revealed the following pathological conditions: The right pleural cavity contained about a pint of colorless liquid. The inferior and middle lobes of the right lung were hepatized, sinking to the bottom of a pail of water. The valves of the heart and pericardium healthy. The muscular tissue of the heart was grayish in appearance, and thought to have undergone fatty degeneration. Upon opening the peritoneal cavity, it was found to be filled with the intestinal contents, but no blood. Commencing at the stomach, and passing along the intestines, no abnormal appearances were noticed until reaching about the commencement of the iliac portion, where a circular perforation large enough to admit the end of the little finger was found, through which the intestinal contents were oozing into the peritoneal cavity. The entire intestinal tract was carefully examined for the remains of old ulcerations, but was normal in appearance throughout. The seat of the ulceration

and neighboring tissues were next examined, but nothing abnormal was noticed, aside from a small quantity of pus on the inner surface of the greater omentum, immediately over the perforation. As the perforation was circular, somewhat larger externally than internally, and the absence of all the bowel troubles usually present in internal ulcerations, I was led to regard the perforation as due to a small abscess commencing in the submucous or muscular coats, opening into the peritoneal cavity on the evening of the 25th, when the abdominal pain was first complained of. The complete perforation I believe to have taken place while straining after the enema, the rapid escape of the liquid contents of the intestines producing instant death by severe nervous shock and the arrest of the heart's action. Several inches of the intestine near the perforation were removed and examined more carefully, and the following pathological conditions noticed: The circumference of the perforation of a dirty grayish color, and surrounded by a plexus of enlarged bluish veins. The omenta were loaded with fat; the liver and heart had undergone fatty degeneration. A single perforating ulcer, without any previous symptoms of diarrhœa, emaciation, etc., to direct the attention of the physician to the abdomen, I believe to be very rare. The pleuro-pneumonia, and indirectly to direct the attention to the chest, and attach a false importance to the abdominal symptoms, would make a diagnosis impossible. If anything of the kind had even been suspected, the castor oil and enema would not have been employed. Opium to relieve pain and arrest the vermicular movement of the bowels would, I think, have been the most appropriate treatment.

A CASE OF LUMBO-COLOTOMY ILLUSTRATING THE BENEFITS OF THE OPERATION.

Reported by G. W. HUNT, M.D.,

CORNISH FLAT, N. H.

Operation performed by Dr. C. K. Briddon, New York City.

The report of the following case will, I think, place upon record additional evidence of the utility and humanity of the operation of lumbo-colotomy in cases of occluded rectum:

Farnham Morgan, aged 46, unmarried; farmer by occupation; had always had good health until eighteen months before the above-named operation was performed upon him. This gentleman consulted me some four weeks before the operation, remarking that he hardly thought it necessary to apply to me for medical advice, as his illness was so slight that it would not, perhaps, need medical treatment. He dated his first deviation from health eighteen months back; he then had a subacute attack of dysentery; after his recovery he noticed an irregular condition of the bowels, more frequent calls to evacuate the rectum, but no decided pain or diarrhœa. For the first year it gave him but little trouble except this inconvenience; the last six months the calls to stool were more frequent, attended with some pain and diarrhœa, with slight discharge of blood and mucus. These symptoms were increasing when he first consulted me, for what he supposed to be piles. I did not have an opportunity to examine him by the rectum at that time, but he grew worse quite steadily for the next three or four weeks, although continuing to work upon his farm and ride about. I was then called to him at his house for the first time, December 26, 1878, and found that the discharges from his bowels were very small and thin, containing blood and mucus; hardly any fecal matter passing; abdomen much distended with gas and accumulated contents, some sickness and vomiting. A rectal examination disclosed a large, hard tumor, filling apparently the whole calibre of the bowel, situated about two and one half to three inches from the anus. Repeated attempts were made to pass by the tumor a female catheter, also a male gum-elastic catheter, but failed. My diagnosis was "carcinoma" of the rectum. From this time to January 1, 1879, the fecal discharges, before very small, ceased entirely, and only the local discharges of blood and mucus continued; sickness of stomach and distention of abdomen increasing rapidly. At this time Dr. Edward E. Phelps, of Windsor, Vt., Professor of Pathological Anatomy at Hanover, saw the case and concurred with me in the diagnosis. The next day Dr. C. P. Frost, of Hanover, Professor of the Practice of Medicine, was called to consult with myself and Dr. Phelps. We agreed that the case was carcinoma of the rectum; that the obstruction was so complete that no more discharges from above the tumor could possibly be procured or hoped for. It was decided to propose to my patient the operation of lumbo-colotomy. He was fully informed of the relief he would obtain from it, also the certainty of a fatal termination of his case in a few days if it was not performed.

He was astonished at the announcement that his disease was cancer, and somewhat surprised to learn that he could be relieved for a time from suffering, and his life prolonged by the proposed operation. He took a day to think over the matter whether to have the operation performed or not; then, prompted by my advice, decided to have it performed. He requested that an experienced and skilful operator be procured, and as the operation has not been performed by any surgeon in this State, that I know of, the attention of myself and Drs. Phelps and Frost was turned to a report of four cases of lumbo-colotomy performed at the Presbyterian Hospital, New York City, by C. K. Briddon, reported in the Medical Record December 28, 1878. It was decided to telegraph to Dr. Briddon. Dr. Briddon promptly responded to the call, and arrived the next day.

The patient was placed under ether, and examined by Dr. Briddon, who pronounced it carcinoma of the rectum, and advised lumbo-colotomy as the only means of prolonging life beyond a few days.

Dr. Edward E. Phelps and Dr. Hubert Sleeper were present and assisted at the operation. The details of the operation performed by Dr. Briddon are well known to your readers. A transverse incision was made half-way between the crest of the ilium and lower rib, half an inch behind the crest of the ilium—centre of incision. The superficial incision five inches in length, careful dissection through lumbar fossa, and down by the side of the quadratus lumborum muscles, through the deep abdominal fascia, indistinctly revealed the colon; it was made to bulge into the wound by forcing air into the colon by the anus; the intestine was opened by vertical incision an inch in length, and carefully fixed to the integument by a proper number of sutures.

The patient rallied well from the operation, and, as soon as it was completed, discharged through the wound a very large amount of fæces, which continued at intervals through the night. The wound

healed kindly, without suppuration, and I removed the last of the sutures the sixth day. Distention of bowels went down, and healthy and free discharges from the artificial opening took place quite regularly. In about six weeks from the operation, which was performed January 3, 1879, patient was taking exercise out of doors. Since then he has been able to walk about his farm, oversee his business, and do some light work; digestion is good, and general appearance nearly up to his former standard of health. He has now, one year from the operation, a discharge from the rectum of some bloody mucus and pus; has but little pain.

His treatment is an anodyne injection at night, and twice a day the rectum is washed out with an injection of glycerine and dilute carbolic acid.

At a recent examination of the tumor I found it larger in circumference, pressing somewhat upon the bladder, and externally rising above the pubes. The patient is grateful for this prolongation of his life, and can hardly believe that his disease is really cancer of the rectum. He is able to ride and walk long distances, and do light work. Suffers but little inconvenience from the opening in the colon; wears an abdominal belt, with folded cloths over opening.

Some points in this case let us consider: the first and most important one, the timely rescue from speedy and impending death; this was a salient point in the patient's mind, for which he is very grateful.

A singularity in his case was his general good health and ability to work up to a few days before the operation, not applying for medical advice, and not entertaining any idea that anything serious was the matter with him. I account for this thus: the discharges from the bowels were loose, and did not irritate the parts passed over as much as a firm stool would, and the looseness prevented accumulation of contents until the tumor rendered the rectum almost impervious. Digestion and assimilation being at the other end of the digestive canal, the local disease did not interfere much with their healthy performance. Another point in the case is the freedom, since the operation, from much local pain, and the general good health, the long and slow progress of the disease; patient seemingly as likely to live another year as well as through the past.

I have purposely delayed reporting this case, that I might test the value of the operation to my patient—measured by time; my patient is more than satisfied with the result thus far.

Death Following a Post-Mortem Wound.—One of the assistant physicians at the University College Hospital cut his hand last November while making a post-mortem. At first the wound attracted no particular attention, but subsequently suppuration set in, and finally pyæmia. He died at about the first of January.—*Brit. Med. Jour.*

ENORMOUS DELAY OF THE PULSE.

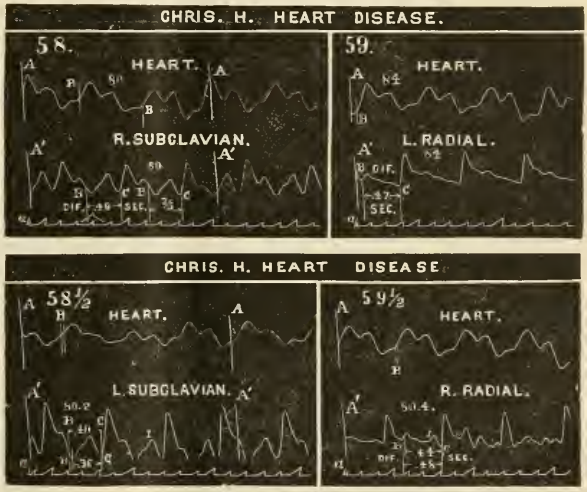
By A. T. KEYT, M.D.,

CINCINNATI, OHIO.

Already my observations* have demonstrated exaggerated delay of the pulse, respectively in mitral insufficiency, aortic obstruction in the form of heavy aortic valves, and aortic aneurism. The case now presented gave an enormous delay of the pulse, and the post-mortem revealed a combination of the three pathological conditions just named.

The case was in the Cincinnati Hospital, and my obligations are due to the physicians in charge for the opportunity to observe it.

Chris. H——, aged 31 years, presented a systolic murmur, distinct over the front of the chest and heard in the back. The murmur was accentuated both at the apex and second left interspace. Second sound clear and loud. Graphic records were taken September 6, 1879. Simultaneous tracings, with accompanying chronogram, were obtained of the heart and left subclavian, of the heart and right carotid,



of the heart and right radial, and of the heart and left radial. These are all shown in the cuts, except the heart-carotid tracings.

Patient died November 16, 1879, and here are notes of the post-mortem, taken from the hospital case-book: Heart weighed fifteen ounces, and was fatty. Just above the aortic valves were two aneurismal pouches, one projecting forward and to the right, the other forward and to the left. The first of these, looking like dilatation of the *sinus* of *Valsalva*, contained no clots; the other was filled with laminated fibrine. The latter was the size of a small apple, and presented a distinct ring about half the diameter of the pouch. It pushed its way in various directions, and pressed upon the pulmonary artery in such manner as to occlude this vessel entirely. Both dila-

*Cin. Lancet and Clinic, March 22, April 19, 1879; N. Y. Med. Record, Nov. 29, 1879.

tations had very thin walls. The aortic valves were much thickened, but were competent by the hydrostatic test. The mitral valve was filled with nodular vegetations, and was incompetent. Right auricle distended and filled with soft clot and fluid. Tricuspid and pulmonary valves presented no disease. Pericardium thickened, and contained twenty-one ounces of fluid. Aorta atheromatous.

Recurring to the tracings, the cardiograms fairly show the phases of the cardiac revolutions, and the beginning of systole cannot be mistaken except in a very insignificant sense. The line B must indicate very closely this beginning. As to the end of systole, I believe it is located near midway of the main descending line. The first pulsation after B, No. 58, probably best shows the time relations of systole and diastole.

In a previous communication,* I well knew that I located the end of systole at the highest point of the main descent, and I still believe that this localization will hold in most cases of perfect traces of normal hearts; but, in such traces as we are able to get of pathological hearts, often the line begins to fall, in consequence of depletion of the ventricle, before the end of systole is reached. The change then transpires in the line of fall, and usually impresses there no definite mark.

According, then, to the interpretation I give the cardiograms in this case, systole, as compared with diastole, is excessively long.

Respecting the arterial traces, the form of both subclavians is *unique*. (The carotid shows essentially the same form.) The peculiarity is carried to some extent into the right radial, but is lost in the left. This singularity of form will not fail to arrest the reader's attention, and its explanation will be sought farther on. A point worthy of notice is, that a just interpretation of these traces will show that the cardiac systolic portion of the pulse is disproportionately short.

But the great lesson of the case concerns the extraordinary delay of the pulse on the systole of the ventricle. Very careful measurements give, as shown (Nos. 58 and 59), $\frac{18}{100}$ second as the delay of the right subclavian, and $\frac{15}{100}$ second as the delay of the left radial. The enormity of this delay is apparent when it is remembered that the normal delay of the subclavian, with pulse at 80, would not exceed $\frac{1}{10}$ second. I believe the retardation of the pulse in this case is the greatest ever observed—certainly the greatest that has been recorded; and if the post-mortem had not furnished the remarkable combination of lesions to explain the delay, it would have been difficult to disarm the criticism that the phenomenon was fallacious and existed only in an error of observation. The three great causes of pulse-retardation coexisted in the case, and the graphic method was competent to demonstrate the amount of retardation so produced.

The physical signs pointed to a cause of systolic murmur located at the pulmonary artery, while the second centre of accentuation of the systolic murmur at the apex indicated, so far, mitral insufficiency; but it was easy to conceive that this murmur might be propagated from the base. As affection of the right side could only produce negative graphic results as regards the pulsations of the heart and arteries, the very positive graphic showings obtained demonstrated the existence of grave disease located at the left side. What manner of disease affecting the left side of the heart could produce the graphic phenomena presented? As to the strange pulse-form, this was to me an enigma. I had never seen its representation, nor allusion to it before. I passed it then without explanation. As to the pulse-delay, the organic conditions producing this phenomenon having been previously ascertained, it was plain that the delay in question must have arisen from one or more of these causes. The limits of pulse-retardation under its causes in single or combined action not having been determined, it was impossible to know with certainty whether such an amount of delay would require for its production all the pulse-retarding lesions; or whether two, or even one, might be sufficient. My observations had shown that the delay is great in mitral insufficiency, enormous in conjoined mitral insufficiency and heavy aortic valves, and distinctly notable in aortic aneurism. From the graphic data in connection with the physical signs I arrived at the diagnosis that the patient was suffering certainly from mitral insufficiency, and probably from added aortic obstruction in the form of heavy valves; but only vaguely did the idea of associated aortic aneurism occur to me. Illustrated now by this case, such extreme delay of the pulse would be accepted by me as diagnostic of the three important pathological conditions in consideration.

The existence of aortic aneurism in association with the other lesions afforded an explanation of the singular pulse-form. The ventricles in their systole compressed the overlying aneurisms, causing the latter to discharge a portion of their blood into the aorta proper, which initiated a considerable wave. This wave, marked 1, was transmitted so much in advance of the true discharge-wave from the heart because escape of blood from the ventricle was delayed by the existing cardiac lesions. The deviation in the upward slope of this wave was probably made by the auricular systole, possibly by default of synchronism between the two ventricles. The ventricle in the latter part of its systole threw quickly a comparatively small amount of blood into the aorta, which accounts for the blending of the second with the early appearing aortic wave.

This description of pulse, it would seem, could only be reproduced by a similar conjunction of conditions, and its demonstration would constitute an important diagnostic sign of these combined lesions.

Thus, step by step, as correct graphic phenomena are connected with well ascertained pathological conditions, will the science of clinical sphygmography be built up.

* N. Y. Med. Jour., July, 1877.

REPORT ON THE USE OF CHLORAL.—The report of the committee appointed by the London Clinical Society to investigate the evils consequent on the use of chloral, is described by the *Medical Press and Circular* as furnishing very little that is new or satisfactory. It contains, however, a few interesting papers; among them are the opinions of eminent authorities in lunacy, who, as a whole, advise against the use of chloral in insanity.

PHILADELPHIA ACADEMY OF SURGERY.—This new association organized Jan. 5th with the election of the following officers: President, S. D. Gross; Vice-Presidents, D. H. Agnew and R. J. Lewis; Secretary, J. E. Mears; Corresponding Secretary, Thos. G. Morton; Treasurer, Wm. Hunt; Reporter, John B. Roberts; Pathologist, S. W. Gross.

Prof. Gross made the society a present of a set of his own works, as the nucleus of a library.

A METHOD FOR THE RADICAL CURE OF HEMORRHOIDS WITHOUT OPERATION.

By CHARLES F. STILLMAN, M.D.,

PLAINFIELD, N. J.

Among the most numerous cases requiring surgical treatment which come before the practitioner, are those suffering from piles, and for these, especially when of long standing and accompanied by more or less prolapse of the rectum, surgery offers us many means of relief: extirpation, by the knife, ligature, or galvano-cautery; absorption, by hypodermic injections, etc. But it seems to me that the main point of treatment—absorption by support and pressure—is overlooked, and this is especially adapted to cure forty cases out of fifty, as the disease is caused by a relaxation of the parts about the anus, due to prolonged constipation, to irregular and prolonged defecation, and any other condition which admits of a filled and heavy rectum bearing down too strongly upon its supports.

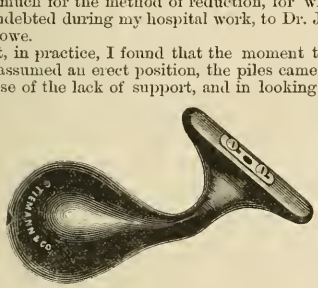
Of course, the less advanced cases can be treated by regulating the bowels with a tonic laxative—the occasional use of a T-bandage when unusual exercise is expected—insisting upon a regular time for defecation, the use of astringent injections, etc., varying for each case. But when the patient exhibits piles of sufficient extent, to be out more or less most of the time, and attended or not with prolapse or hemorrhage, the method of procedure I am about to detail will be found especially useful.

Place your patient in the knee-chest position, and after anointing the parts with some lubricator, gently exercise traction, as in a hernia reduction, and the force of the atmospheric pressure will cause the piles to return. Follow them with your finger until each pile is in place.

This reduction cannot be effected in severe cases, unless the patient is placed in this position, and all cases of piles should be reduced in this manner.

So much for the method of reduction, for which I was indebted during my hospital work, to Dr. Joseph W. Howe.

But, in practice, I found that the moment the patient assumed an erect position, the piles came down, because of the lack of support, and in looking about



to find something which would supply the deficiency, the supporter shown in the engraving was brought to my notice.

It is of rubber, semi-solid, and very flexible, and of the correct shape for introduction and retention in the rectum.

Having been well lubricated, it is passed into the rectum on the withdrawal of the finger, and is kept in place there by a T-bandage and compress. One napkin is passed around the waist, and the two ends fastened with a safety-pin, and a second napkin having a folded one fastened to its centre for a compress over the anus, is passed between the legs and secured to the other napkin in front and behind with safety-pins, being drawn up as tightly as is consistent with the comfort of the patient.

The support produced by the combination of the rubber pessary and the T-bandage is both external and internal, producing rapid absorption and cure without pain, and affords great relief to the patient.

I usually place a mirror at such an angle that the patient can see the whole procedure, and I have yet to find one that cannot practise it upon himself, as he is directed to do each morning on rising, each night on retiring, and after each defecation, although in most cases the latter only will be necessary. Combine with this the use of the usual laxative pill containing the following ingredients, with colocynth added if the constipation is obstinate:

℞. Ext. nuc vomicæ..... gr. vi.
Pulv. rhei.
Sodii bicarb.....āā gr. xxx.

M. Fiat pil. No. xxx.

One to be taken before each meal and at bedtime.

These are the essential features of the procedure, and it is in the combination of the factors just detailed, and not the use of any one, which insures the success the writer has met. And as he has not met with any description of it, or come in contact with any one who has employed it in its details, he has felt impelled to place it before the profession as a slender contribution to that department of surgery.

Progress of Medical Science.

Borocitrate of Magnesia a Remedy for Urinary Calculi.—Dr. Koehler, of Kosten, Germany, states that he has for a long time employed the borocitrate of magnesia with satisfactory results in the treatment of renal and vesical calculi, gravel, and vesical catarrh. Becker showed, in a paper published in 1868, that the secret remedy employed by Paracelsus in the treatment of lithiasis, and called by him "ludus," or "cevillus," was boracite or borate of magnesia. Becker was himself convinced of the value of the remedy, and published a number of cases in which he had employed it with success. Boracite is readily soluble in citric acid, and the borocitrate of magnesia is obtained from the combination. It is a white powder, with a sour taste and without smell. Koehler reports five cases of renal calculi and gravel in which he employed it. In all of them the gravel rapidly disappeared from the urine; the larger stones seemed to have decreased in size, and their evacuation was hastened by the diuretic action of the remedy. One of the patients passed, while under treatment, a uric acid calculus as large as half a pea. This was placed in a saturated solution of the salt, and in eight days it was reduced to sand. In all of the cases treated by Koehler, the gravel and calculi were of the uric acid variety. He recommends it also for the uric acid infarction of new-born children. He prescribes a two or three per cent. solution, and gives a teaspoonful every hour; the urine is usually passed after the second or third dose. In chronic vesical catarrh, the borocitrate of magnesia proves very useful; it increases the flow of urine, and very soon makes it clear and trans-

parent. It acts still better and more rapidly when injected directly into the bladder. For adults, Dr. Koehler prescribes a mixture of one part of the salt to two parts of powdered sugar, with the addition of one drop of oil of lemon to 120 grm. (℥iv.), of this a teaspoonful is taken in half a glass of water three times a day for months.—*Berliner klin. Wochen.*, No. 44, 1879.

Aural Disease Influenced by the Condition of the Teeth.—Dr. Samuel Sexton has made very valuable observations on 1,500 aural cases in which the teeth were examined. In one-third of these cases the aural disease seemed to be influenced by the condition of the teeth through the sympathetic relationship of these parts, aural hyperæmia or inflammation being thus induced through the vaso-motor system.

Dr. Sexton draws attention to the frequency of aural attacks during the eruption of the first teeth, or their early decay, influences that are often co-existent with catarrhal affections of the buccal cavity, throat, and naso-pharynx, causing a sympathetic hyperæmia of the ears, although not always accompanied with pain. He believes that such irritation influences the ear through the Eustachian tubes less often than many suppose. Especially when an intercurrent "cold" supervenes, the gravity of these cases is increased, and the result may be a painful affection of the ear, or, if subacute, deafness may be the prominent symptom; indeed, the latter, when unrelieved, sometimes results in deaf-mutism.

Frequently, decay of the sixth-year molar, which is the first tooth of the permanent set, causes a great amount of distress in both the teeth and the ears, and in fact, from this time on until the rest of the teeth (excepting the wisdom) are cut, at the twelfth year, premature decay may take place, and thus increase the irritation of second dentition.

The eruption of the wisdom teeth, when difficult, is also found to cause the sympathetic action under consideration. The loss of the second teeth is by no means attended with pain in all instances, for, indeed, nearly all them have been known to be lost without occasioning any other symptom than deafness or tinnitus aurium.

Both furuncles and collections of cerumen in the external auditory meatus may be found in connection with carious teeth, and attention to the latter under these circumstances is advisable.

Amalgam fillings in the teeth are liable, under some circumstances, to poison the patient, the attrition to which they are subjected liberating the mercury which enters largely into their composition, and which afterward enters the intestinal tract.

The plates that are used to support artificial teeth irritate the mouth when not properly made, and when they are, as is frequently the case, worn over carious fangs, inflamed palate or gums, collections of tartar on the teeth, decomposed food, and purulent secretions, the consequences are more serious.

Of all the plates in general use, Dr. Sexton's observations lead him to believe that those made of vulcanite are the most inimical to health, partly on account of the toxic effects of the large quantity of sulphide of mercury used in their manufacture, and partly owing to the local irritation of the mucous membrane of the mouth with which they lie in contact. A carcinomatous affection of the jaw has been known to arise from the persistent use of these plates.

More frequent oroscopic examinations in all aural cases are recommended by the author, and it is urged also that further investigations of the effects of the various metals worn in the mouth should be made, in order that it may be ascertained whether or not they exert a deleterious influence on the patient's health.

Horizontal Extension and the Porous Felt Jacket for Curvatures of the Spine.—Dr. Benjamin Lee, in a paper read before the Pennsylvania Medical Society, describes the advantages he has found by horizontal extension in spinal curvature; he also advocates the substitution of porous felt for plaster-of-Paris as a material for jackets. Dr. Lee had for a number of years been accustomed to treat patients with idiopathic lateral curvatures by the daily use of the swing in mild cases, and by the jacket in the severe ones. He found, however, so great pain and discomfort produced by vertical suspension, that he resolved to substitute horizontal extension for it. He obtained equally good results in this way, and, though not giving up suspension entirely, employs extension oftener. His apparatus is a sort of rack with transverse rollers, on which the patient lies, and to which the head, hands, and feet are attached. Extension is made by levers. When a plaster jacket is to be put on, a number of strips of bandage cut so that they will reach around the chest and overlap, are soaked in plaster-of-Paris and laid upon the rack; the patient is then placed face downward on these; extension is made, and the plaster strips brought about the body and moulded on.

This is the general method. The details are minute, and require an illustration. Dr. Lee only makes a mould for a cast of the chest in this way, and then moulds a porous felt jacket on this cast. He considers that the regular practice of horizontal extension as a gymnastic exercise is of great use in the idiopathic curvatures of young girls. His own apparatus is being constantly used for this purpose.

The porous felt jacket is recommended as superior to the plaster-of-Paris for the following reasons: 1. Its permeability to air and moisture; 2. Lightness; 3. Adjustability. By heating it, any desired change in shape can readily be made. 4. Ease of removal. 5. Cleanliness.

Dr. S. T. Davis's solution for saturating bandages is commended as causing them to dry with the greatest rapidity. It consists of sulphate of potash ℥ij., common salt ℥ij., water Ovi.—*Trans. Med. Soc. State of Penn.*, 1879.

Hinderance to the Respiration by Disease in the Nose.—Dr. D. H. Goodwillie, in a paper read before the Canada Medical Association, refers to the deviation of the cartilaginous septum and hypertrophy of the soft parts as the chief causes of nasal obstruction. For the cure of the former condition he showed a set of excising nasal forceps. On one blade of these forceps is a circular, ring-shaped knife, and this cuts against the flat surface of the other blade. Dr. Goodwillie simply applies the forceps and cuts out the deviating part. He reports a number of successfull cases.—*Can. Med. Record*, Dec., 1879.

Acute Orchitis treated with the Roller Bandage.—Take a roller bandage one inch wide, four yards long, and thoroughly imbued with starch. Seize the affected gland with the left hand so as to make a pedunculated tumor of it, and apply four turns of the bandage around the neck of the tumor. Then wind the bandage about the tumor itself in such a way as to effect firm compression. The patient should be kept in bed and the bandage be applied morning and night; no other treatment is necessary. In a few days the swelling will all be removed, but

the bandaging should be continued a little longer, to prevent relapse. This method will be found less annoying and painful than that of using adhesive plaster.—*Dr. L. A. Dugas, in N. O. Med. and Surg. Journal*, Jan., 1880.

A Simple Apparatus for the Treatment of Fractures of the Clavicle.—Dr. L. A. Dugas, in the *N. O. Med. and Surg. Journal* for January, describes his method of treating fractures of the clavicle. He discards all axillary pads as inefficient and injurious. To meet the usual indications in this fracture he prepares and applies an apparatus as follows: a square yard of unbleached shirting is cut diagonally so as to form two triangular pieces. To each of the acute angles of one of these pieces a three-inch bandage, four yards long, is sewed. This completes the apparatus. The displacement is then reduced by carrying the shoulder upward, backward, and outward. Then the middle of the long side of the triangle is applied beneath the elbow, leaving a margin of four inches behind, the right angle being directed toward the fingers. One of the acute angles with its bandage is now carried between the arm and chest, up to the fractured clavicle, around the back of the neck, over the sound shoulder in front and beneath the axilla, and finally around the arm just above the elbow. The other end of the strip is then carried up, in front of the forearm, to the sound shoulder, behind and beneath the axilla, and around the chest and arm, so as to meet its fellow and be tied to it. Finally, the margin left projecting behind the elbow should be elevated, doubled, and stitched, so as to prevent the elbow from sliding out. The strips encircling the arm should also be stitched to prevent displacement.

This bandage is said to be a very comfortable one, easily applied, and efficient.

Abstract of an Experimental Research on the Physiological Actions of Drugs on the Secretion of Bile.—Dr. Wm. Rutherford communicates to *The Practitioner* an abstract of his experiments with hepatic stimulants. They were made upon fasting dogs which were curarized to prevent the struggles and interference of the animals.

The process was as follows: About eighteen hours after the last meal the dog was curarized by injecting .020 grms. of curara into the jugular vein. Owing to the consequent motor paralysis, artificial respiration had to be maintained during the experiment.

After the curarization, incisions were made, and a glass canula tied into the common bile-duct; the gall-bladder was emptied and the cystic duct tied. The animal was then wrapped up in cotton-wool and his temperature kept normal. The drug to be experimented on was then injected into the duodenum, and its effect upon the flow of bile or the intestinal secretion watched.

A large number of preliminary experiments were made and precautions taken. In the first place the dog was the animal chosen, because his digestion most nearly resembles that of man. Chloroform was not used, because it of itself was found to be a hepatic stimulant. Curara was proved to have no effect on the hepatic function. Temporary biliary fistulæ were made, because all previous experiments with permanent ones had proved unsatisfactory and contradictory. The coefficient of the secretion of bile—that is, the amount secreted in a unit of time for every unit of body-weight—was determined. Analyses of the bile secreted, before and after giving a hepatic stimulant, were made, and they showed that although the bile, when secreted in larger amounts, is more watery, yet the total amount of bile constituents is also increased. Post-mortems were made in every case, and the intestinal mucous membrane examined. These post-mortems showed that there are purely intestinal and purely hepatic stimulants; also that over-stimulation of the intestinal glands reduces the amount of bile secreted, even though the intestinal stimulant is also a cholagogue. The injection of the drug directly into the duodenum was thought to make no difference in its action, except in the case of calomel. This drug was shown to have no effect on the liver itself. When given by the stomach, however, a portion is turned into *corrosive sublimate, which is a cholagogue.*

The following are the results of the experiments with the special drugs:

Croton oil has scarcely any influence on the liver.

Magnesium sulphate diminishes the secretion of bile.

Manganese sulphate stimulates the intestinal, but not the hepatic secretion of the dog.

Castor oil diminishes the flow of bile when purgation is well established.

Ammonium chloride is said, in ten or twenty grain doses, to produce diuresis, diaphoresis, nervous exhilaration, and intestinal peristalsis. It is highly recommended in "torpor of the liver." It diminishes the biliary secretion of dogs, however, and presumably in man.

Gamboge is a duodenal irritant; nevertheless, it diminishes the flow of bile. It follows that *duodenal irritation* does not necessarily cause increased flow of bile.

Resina podophyllio is a powerful hepatic as well as intestinal stimulant. In violent purgation by it, however, the secretion of bile is lessened.

Iridin and *euonymin* powerfully stimulate the liver and mildly stimulate the intestine. The dose of iridin is four grains, that of euonymin two grains; two grains of hyoscyamus should be added to prevent griping. The drug is best given at night, followed by a saline drink in the morning. Iridin is the more powerful remedy of the two.

Hydrastin, *Resina juglandis*, and *Resina baptisiæ* moderately stimulate the liver, and mildly stimulate the intestine. The three drugs are commended to to the attention of the physician.

The general result of the experiments showed that powerful purgation diminished the bile secretion. This is done, probably, by lowering the blood pressure in the liver, and by sweeping out materials that would otherwise go to make up the bile. It is suggested that a purely intestinal stimulant may benefit the liver by carrying out matters from the intestine which would otherwise be absorbed and hamper hepatic action.

In estimating the value of these experiments, several facts should be remembered: the subjects were dogs; they were under the influence of a powerful drug, and life was kept up by artificial respiration; the biliary apparatus was interfered with surgically; the drugs used were injected into the duodenum, not the stomach; the dogs were healthy, their livers normal; the experiments referred only to the bile-secreting, not the bile-expelling function. Taking into account all these things, however, we can still say that the experiments have demonstrated some important physiological facts, and furnish valuable indications for clinical study.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 14, 1880.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Within the past few years the Medical Society of the State of New York has made a reputation for useful work which is not equalled by any similar organization in the country. The session just closed is no exception to the rule in being an interesting and profitable one to all concerned. The attendance of delegates was large, and every district of the State was well represented. The business of the meeting was despatched with a readiness which reflected credit upon the committee having the matter in charge, and as much time as possible was devoted to the reading of papers and to scientific discussions. The variety of material presented was sufficient to satisfy the wants of all, and took in a wide range of subjects. It is noticeable that authors are becoming more and more impressed with the idea that the majority of practitioners are interested in facts which have a practical bearing, and which tend to help them in the daily exercise of their calling. Many a youngster went home with a new idea, and not a few veterans were amply repaid for the time and attention they gave to the meeting.

The necessity for curtailing the time for reading papers had the merit of compelling authors to present their points in the briefest possible manner, and of giving a suitable variety to the business of the sessions. The discussions were not so easily shortened, and in some instances, with the best of intentions on the part of the participants, became somewhat uninteresting, if not tedious.

The President, Dr. H. D. Didama, of Syracuse, delivered an admirable inaugural address, and, in the choice of his topic, showed himself thoroughly alive to the necessities of the hour. His pleasant allusion to the increase of medical students was hardly congratulatory in character: in fact, in view of his suggestions for a higher standard of medical education, they were a trifle sarcastic. The absolute necessity for higher medical culture was dwelt upon with great earnestness, and the suggestions offered were of a character that commend themselves to thinking and practical men.

The necessity of preliminary education, the increase in the length of the lecture term, compulsory attendance upon lectures, frequent written examinations, and final examination by an independent board, were matters to which allusion has often been made, but it was the first time that they were presented in so direct manner by the presiding officer of the Medical Society of the State of New York—the first time that an opportunity was offered for a declaration of opinion by the Society. This being the case, we are not a little disappointed in the course taken by the committee appointed to report on the address. While acknowledging the necessities for the reforms named, and especially that one referring to independent examinations, the committee seemed indisposed to make any recommendations, and virtually acknowledged that the difficulties in the way of the accomplishment of such an end were practically insurmountable. The majority of the profession think differently, are not willing to believe that no changes can be made, and agree with Dr. Didama in the belief that the obstacles are not so great as they seem, and that a determined effort in the right direction may be rewarded with success. The suggestions of the President regarding medical education in his inaugural are more elaborately presented in his annual address, and will be read with profit by all interested in advancing the standard of medical qualifications.

THE SOCIAL POSITION OF THE DOCTOR.

Dr. J. Milner Fothergill has been writing letters to the *Philadelphia Medical Times*, and in the later ones he discussed the social position in England of the doctor and of the doctor's wife. His remarks were somewhat severe, particularly as regards the wives. These, he said, if married to country doctors, had no position at all, but were virtually social pariahs and outcasts. The editor of the *British Medical Journal* criticised these statements quite sharply, and a controversy upon the matter has arisen which brings it into some prominence. In the United States it is probable that the question of social position occupies the smallest possible share of the doctor's attention. Still he cannot always ignore it; and an occasional discussion of the subject is pertinent.

The fact that a man is a physician is one which, of itself, has very little to do with any position of society he may take. If he has the means, the inclination, and the manners, he can enter as high a circle as any one; and is neither helped nor handicapped, as a rule, by his being a professional man. If a doctor, as is the case generally, makes no effort for special

social recognition, he takes such a place as any other person does of similar circumstances of education or breeding.

In large cities, and particularly in New York, the medical profession makes quite a large and important element in social life. We have here many young men of means and education, who have settled in New York because they prefer to live in such a city, and can afford to wait a number of years for their practice. There is always a full representation of this class at receptions, dancing-parties, Germans, and dinners. They will be found in all the clubs also. The older members of the profession take more, of course, to dinner-parties and club-life. And here they are quite prominent factors.

We speak of "social position" because, although this is a republic, the existence of social distinctions is a not inconspicuous fact. Still, in many parts of the country, these distinctions, above a certain point, are not very strongly marked. Even in cities a person whose manners and speech rank him a gentleman will find few to snub him on account of his occupation, his ancestors, or his poverty.

The social position of the doctor in this country is not, on the whole, a very high one; because the individual doctor has not the means, and often it must be confessed, not the education or taste, to make it such. He can, however, be whatever he chooses, or at least whatever nature gave him capacity to be, unless accidents of poverty or domestic life drag him back.

Social position is one of those minor aims of life which shipwrecks more people than grand ambitions do. It is not a thing for which men should struggle. Physicians are expected to be gentlemen, and their social ambition need go no farther.

INFECTIOUS PNEUMO-ENTERITIS.

It is estimated that $20,000,000 are lost to this country every year from infectious pneumo-enteritis, or, as it is popularly called, hog-cholera. The disease is more extensive and malignant than any other of the common affections of domestic animals. Its study, therefore, is very important from an economic point of view. It has peculiarities, also, which give it a great deal of pathological interest. The labors of Klein in England, and of Detmers and Law in this country, under the direction of the U. S. Commissioner of Agriculture, have brought out many new facts, and our knowledge of the disease is now tolerably full.

Infectious pneumo-enteritis, as it is called by Klein, has been known in Europe for over a century; it has ravaged the herds of the United States for thirty or forty years.

It is a purely and actively contagious disease, manifesting itself with the symptoms of a continued fever, bronchial and pulmonary inflammation, more or less enteritis, uniform involvement of the lymphatic system, and some one or more of the serous membranes of the trunk.

It varies much in virulence, but an ordinary attack comes on slowly. The pig becomes listless and inactive, loses its appetite, and is generally constipated; the thin parts of the skin become reddened, and finally petechial; the inguinal glands are always swollen; cough develops, and rapid respiration; the thermometer shows a high fever, and, later on, examination may detect consolidation of the lungs. The animal emaciates; is disinclined to stir; it shows evidences of pain in the abdomen; mucus hangs about the mouth; the eyes are bloodshot; a specific offensive smell is emitted; it staggers about, and finally drops down to die of exhaustion. The disease lasts from one to two weeks.

About eighty per cent. die, and those that survive are rarely of any further use. Upon a post-mortem examination, evidences of bronchitis, and of more or less lobar and lobular pneumonia, are found in the lungs. In earlier stages, many small emboli are found, which swarm with a peculiar kind of bacteria, called by Detmers *bacilli suis*. In the intestines are pathognomonic changes in the form of morbid growths upon the walls of the cæcum and colon. They sometimes occur in other parts of the alimentary canal, and even upon the conjunctiva and parts of the skin where there have been wounds. These little tumors are round, more or less elevated and pedunculated, and vary in size from that of a pin's head to a quarter of a dollar. They are composed of proliferations of the intestinal epithelium, contained in a stroma of new connective tissue. They are soft and easily broken down. The *bacilli suis* are described by some as swarming in the midst. The lymphatic glands are enlarged, and the pleura, pericardium, and peritoneum are either one or all affected. The morbid changes vary greatly in the prominence with which they affect the different organs. Sometimes it is the lungs chiefly, and sometimes the intestines or serous membranes; but the most constant pathological changes are in the lungs and intestines. The blood is said to contain many bacteria of the kind mentioned.

The infecting poison is a very active one. It may enter the system by the lungs or the stomach, or it may be inoculated. It is easily decomposed, but cold only locks up its powers, without destroying them. It affects other animals than swine, notably the mouse, which, being diseased, may carry the contagion. The infectious principle exists in the secretions and organs, but it is doubtful if the blood is always infectious. It may be carried by water as well as by air. Klein discovered it to be a particulate body; Drs. Detmers and Law seem to think it is a variety of bacteria, the *bacillus suis*, an organism which

was cultivated and studied microscopically by them. A belief in the fact that this organism is the *contagium vivum* is asserted with a positiveness not warranted by the facts.

Dr. Detmers cultivated these *bacilli suis*, and describes them as at first minute round bodies, or bacilli-germs, about .0007 mm in diameter. These gradually lengthen into rod-bacteria, which become very long, and then, breaking up, give birth to numerous *bacilli*-germs again. These sometimes have a tendency to unite into viscous clusters. It is suggested as most probable that such clusters are formed in the narrow capillaries of the lungs, constituting the emboli there found; these emboli subsequently set up a pneumonia.

As regards treatment, it seems to be the wisest plan not to attempt any. Rigorous precautions should be taken to prevent the disease; but, if it has once entered a herd, all attempts at dallying with the poison are unwise. As soon as a pig is discovered to have the disease, it should be removed from the herd, and when dead, should be buried deep in the ground. The poison incubates from three to fifteen days, and the latter period of time must be waited before one can be sure that the herd is safe. Disinfectants should be freely used among the animals, chloride of zinc being probably the best. By vigorous measures of this kind the disease may be stamped out eventually. It should be the duty of the State, or general government, to make laws against the selling or transportation of the diseased animals.

The report of the Commissioner of Agriculture, which contains the results of his investigations of this disease, and from which we take many of the above facts, is an extremely creditable one. It is illustrated with micro-photographs and colored lithographs, the latter being exceptionally good specimens of a generally inane branch of art. The pathological work has been very conscientiously done, and, though showing some crudeness in the matter of its theories, makes, on the whole, a valuable contribution to the science of morbid processes. The fact that within two months the United States Government has published three works of high scientific interest is extremely gratifying.

BILL FOR CREATING A NEW LUNACY COMMISSION.

As stated in our last week's issue, a bill has been introduced into the State Legislature for the creation of a new Lunacy Commission. It provides that the Governor shall appoint three additional members to the State Board of Charities, two of whom shall be physicians unconnected with any insane asylum. The State Board of Charities, including these three new members, is to constitute the State Commission in Lunacy, and is to have all the powers and duties heretofore vested in the State Commissioner in Lunacy. In its annual report, the Board is to give such facts and make such suggestions as may be deemed useful for the improvement of the lunacy administration of the State. The Board is also empowered to appoint a Secretary in Lunacy, who shall be a physician and not a member of the Board. To this officer the duties of examination and supervision may be delegated. He is to receive a salary of $4,000 a year.

The committee who drew up the bill have, as will be seen, acted on the principle that it is wisest to ask for but little in the beginning. The proposed law makes only a few changes; these are, however, important ones.

Under the old law the State Commissioner was hampered by the personal influences about him, and by the fact that his authority was in part divided with that of the State Board of Charities. The present bill proposes to concentrate the power in a single experienced and able Board. To this the Secretary in Lunacy must be responsible. As the term of service of the members of the Board is eight years, it is unlikely that he will be subject to the caprice of governors, or the changes of parties. The addition of three members to the Board, two of them medical men, will enable that hitherto overworked body to pay much greater attention to insane asylums.

The arrangement proposed by the bill is also an economical one, nor does it throw any increased burden on the executive department.

Thus, although the apparent difference, under the new plan, is only an increase by three in the membership of the State Board of Charities, the real difference, in a concentration of authority, in an infusion of special knowledge and increased strength, and in an elevation of the supervising power above political and personal influences, is very great. The bill is wisely drawn, and it should be made a law. If those desiring insane asylum reform can get anything at present, they ought to get this.

It must be confessed that a glance from the bill to our city asylums, with their twenty-five hundred insane herded together under the care of one scientific gentleman, leads us to feel that reforms move slowly. But, as the mills of the gods are said eventually to triturate to extreme minuteness, we can await in patience that desirable consummation to the existing abuses.

The committee print along with the bill a letter from Dr. Henry Maudsley, of England, indorsing the lunacy commission of that country. There is also given a brief history of the present movement for asylum reform, in which the fact is forgotten that the movement was initiated and put on its feet by Miss A. A. Chevalier, of Boston. A valuable letter written by Mr. Dorman B. Eaton is also printed. It gives an analysis of the lunacy laws of Great Britain as compared with those of this State.

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

SEVENTY-FOURTH ANNUAL MEETING,

Held in Albany, February 3d, 4th, and 5th, 1880.

TUESDAY, FEBRUARY 4TH — FIRST DAY — MORNING SESSION.

THE Society met, pursuant to adjournment, in the city of Albany, at 10 o'clock A.M., and was called to order by the President, DR. HENRY D. DIDAMA, of Syracuse.

Prayer was offered by REV. ALBERT FOSTER.

INAUGURAL ADDRESS.

The President then delivered his inaugural address, in which he thanked the Society for the honor it had conferred upon him, spoke of the increased attendance in our medical schools as a comforting assurance that the race of doctors is not in imminent danger of perishing from the face of the earth, 2,282 students having attended during the past year, a healthy increase of 267 over the number last year reported; 608 graduates in 1879 – an increase of 82—66, or 9 per cent., failing to receive diplomas. He then spoke of the demand for a higher standard of medical education. It would not be unwise to urge the adoption of some uniform plan, such as related to preliminary qualifications, longer terms, compulsory attendance, frequent written examinations, and final examination by some independent board selected either by this Society or the regents of the University.

It would seem that some modification of the law forbidding physicians to divulge information derived at the bedside of the patient should be made. Gross injustice may result as the law now stands.

It would be well if some law was passed that would protect physicians and surgeons from prosecution by scoundrels who acted under the pretence of securing damages far malpractice. The plaintiff should be required to give bail for costs.

A suggestion regarding holding meetings for purely scientific purposes was presented for the careful consideration of the Society, as received from a correspondent, without making any recommendation.

On motion by DR. N. C. HUSTED, the President's address was referred to a special committee.

ANNOUNCEMENT OF COMMITTEES.

The President then announced the following committees:

For Business Committee — Drs. A. Hutchins of Brooklyn, B. F. Sherman of Ogdensburg, and Miles B. Hyde of Cortland.

For Committee on Credentials—Drs. J. W. S. Gouley, of New York, L. E. Felton, of St. Lawrence County, and H. B. Allen, of Onondaga County.

RELATIONS BETWEEN IMPERFECT ACTION OF THE OCULAR MUSCLES AND FUNCTIONAL NERVOUS DISEASES.

DR. GEORGE T. STEVENS read a paper upon the above subject, which modified his views first presented eight years ago, and embodying the principle that functional nervous diseases are, beyond all others, dependent upon anomalous refraction of the eyes, by the addition of imperfect action of the muscles of those organs, so that his modified view would read functional nervous diseases are, beyond any and all other causes combined, dependent upon anomalous conditions of refraction and accommodation of the eyes and imperfect action of the muscles of those organs. Cases were related: one of epilepsy relieved by relaxation of spasm of the ciliary muscles; and one of hystero-epilepsy. Several cases of like character were given; also cases of chorea.

The discussion was opened by DR. ROOSA, of New York, who stated that it had been shown conclusively that a great many children had chorea who had no error of refraction; and also it had been shown that children had recovered from chorea long before any one knew about the use of spectacles. However, the notion that irritation in the eyeball might cause reflex troubles in other parts of the body, no gentleman of experience doubted. That fact had been recognized, more or less, ever since the function of the ciliary muscle had been accurately determined. He thought that the facts which had been presented should lead to a great deal of caution in thinking that glasses will cure any large percentage of cases of epilepsy, anæmia, chorea, neuralgic headaches, or other nervous troubles.

DR. A. JACOBI, of New York, remarked that chorea was due to a number of causes, as was well known, and Dr. Stevens had added another cause, which, perhaps, might explain some of the cases which heretofore had been regarded as idiopathic.

DR. STEVENS remarked that the practical fact was not so much with reference to the use of glasses as that the nervous trouble in his cases was cured by treatment directed to the ocular muscles, and he believed that in a good proportion of cases of functional nervous diseases the cause would be found to exist in irregularities in the action of those muscles.

COMMUNICATIONS FROM COUNTY MEDICAL SOCIETIES.

DR. W. M. CARPENTER, of New York, presented communications from the Medical Society of the County of New York, which were referred to appropriate committees.

THE SECRETARY presented a communication from Broome County, relating to abuse of medical charities.

DR. JAS. P. WHITE, of Buffalo, presented a communication from the Erie County Medical Society relating to vivisection, and also a communication from the Buffalo City Medical Society upon the same subject. Referred to the Business Committee.

DR. N. C. HUSTED reported as delegate to the New Jersey Medical Society.

DR. ALEXANDER HUTCHINS, of Brooklyn, then read a paper on

FORCED ALIMENTATION.

The point in practice is to recover nutrition. A family that partakes well of all meals is exceptional. There may be no desire for food, but yet it may be possible to cultivate a desire. How is it possible to cause the needful amount of food to be taken appropriately? Will the systematic placing of food in the stomach finally restore the appetite? It can; but, to do so, precise and intimate directions must be given, and the patient must be placed under the uncompromising direction of the physician. The heathen sympathetic parents must first be converted. It is less a question of what shall be eaten than that something shall be eaten. It should be taken in as large quantities as possible, and at suitable intervals, as a stern duty. The operation may be strictly mechanical at first. At first food should be used not requiring mastication. Solids or semi-solids are

preferable over liquid foods. The idea is to habituate the stomach to the presence of food. One essential direction is that the food should be taken at regular intervals, extending over a long period. Commence before getting up in the morning, and continue for eighteen out of twenty-four hours. Free use of water is to be insisted upon as a requisite in forced alimentation.

COMMITTEE OF INVITATION.

On motion, the Committee of Arrangements was authorized to invite members of the Legislature who are members of the regular medical profession, to be present and participate in the transactions of the Society.

Dr. W. W. Potter, of Batavia, then read a paper on

RECTAL ALIMENTATION.

The subject was considered under three heads: 1. Stomachical rest, 2. Methods of alimentation, 3. Conclusions. Absorption of the material is not the sole manner in which material enters the blood. The most reasonable explanation was found in the retrostaltic action of the intestines, so that the pabulum is carried up and meets the descending digestive juices. There were two causes which tend to narrow the field of usefulness for this method of sustaining nutrition: 1. Want of proper confidence upon the part of the profession; and 2. Prejudice upon the part of the laity.

The two papers were discussed by Drs. Kneeland, Allen, Van Derveer, Wey, Palmer, Jacobi, Stoddard, and Ward.

COMMITTEE ON THE PRESIDENT'S ADDRESS.

The following Committee on the President's Address was announced: Drs. E. M. Moore of Monroe County, W. C. Wey of Chemung, J. V. Kendall of Onondaga, and N. C. Husted of Westchester.

REMOVAL OF SPLINTER OF WOOD FROM THE CORNEA.

Dr. David Webster, of New York, reported a case of the above character occurring in a child about three years of age. He regarded it as a unique case. The splinter and a photograph of the eye were exhibited.

FOREIGN BODIES IN THE EYE.

Dr. Charles S. Bull, of New York, read a paper on the above subject which contained a concise account of several cases, such as a fragment of steel in the vitreous, fragment of steel in the anterior chamber, with traumatic cataract. The paper was discussed by Dr. Roosa.

The following papers were read by title and referred to the Committee of Publication:

"Cerebral Thrombosis following Operation," by Dr. T. H. Squire, of Elmira; "Memoir of Dr. Joseph Bates," by Dr. M. L. Bates, of Columbia; "Memoir of the late Dr. D. Griffin Sweet," by Drs. Hamlin, Brown, and Willard; "Physiology of Opium-Poisoning," by Dr. Nelson Sivison, of Burdette; "On the Duties and Responsibilities of Medical Men in Relation to School Hygiene," by Dr. Harvey Jewett, of Canandaigua; "Endemic Pleuro-Pneumonia in New York in the Last Twelve Years," by Dr. James R. Leaming, of New York; "A Case of Diaphragmatic Hernia," by Dr. E. D. Ferguson, of Troy; "Tapping the Abdomen," by Dr. F. Hyde, of Cortland; "Memoir of Dr. H. W. Dean," and "Memoir of Dr. M. Stein," by Dr. E. V. Stoddard, of Rochester.

CASES OF THE ANKLE-JOINT IN CHILDREN.

Dr. V. P. Gibney, of New York, read a paper on the above subject, which was discussed by Dr. E. M. Moore, of Rochester, who did not exactly accept the expectant plan [see Record, vol. xvii., 126], and by Dr. L. A. Sayre, of New York, who thought it well to aid nature in effecting a cure.

The Society then adjourned to meet at 3 P.M.

FIRST DAY.—AFTERNOON SESSION.

The Society was called to order at 3 P.M. by the President, who announced the following

COMMITTEE OF NOMINATION.

For First Senatorial District—Dr. J. C. Hutchison, of Kings Co.; *for Second Senatorial District*—Dr. D. Greenesey, of Dutchess Co.; *for Third Senatorial District*—Dr. A. Van Derveer, of Albany Co., *for Fourth Senatorial District*—Dr. E. M. Lyons, of Clinton Co.; *for Fifth Senatorial District*—Dr. H. S. Crandall, of Madison Co.; *for Sixth Senatorial District*—Dr. T. H. Squire, of Chemung Co.; *for Seventh Senatorial District*—Dr. J. V. Kendall, of Onondaga Co.; *for Eighth Senatorial District*—Dr. Chas. C. F. Gay, of Erie Co.; and Dr. S. O. Vander Poel, of Albany Co., appointed by the President.

Dr. Wm. H. Bailey, Chairman of the Committee of Arrangements, reported the names of the following gentlemen as members by invitation, and they were duly elected:

Drs. Montrose A. Pallen, of New York; C. D. Alton, of Hartford, Conn.; Wm. J. Lewis, of Albany; P. R. Furbeck, of Gloversville; James A. Deane, of Catskill; Geo. T. Stevens, of Albany; C. E. Nichols, of Troy; Conant Sawyer, of Au Sable Forks, Essex Co.; F. S. Greene, of Coxsackie; W. M. Carpenter, of New York; A. B. Hinsted, of Albany; C. H. H. Sayre, of New York; Lewis Balch, of Albany; S. O. Vander Poel, Jr., of Albany; Wm. Hailes, Jr., of Albany; W. A. Hall, of Fulton, Oswego Co.; W. W. Munson, of Otisco; G. W. Earle, of Tully; P. J. Keegan, of Albany; L. C. Dodge, of Ronse's Point, Clinton Co.; G. D. Dunham, of Plattsburg; H. L. Fellows, of Albany; C. B. La Moure, of Albany; E. V. Stoddard, of Rochester; H. R. Starkweather, of Albany; D. H. Cook, of Albany; Robert R. McIlvaine, of New York, and delegate from the Ohio State Medical Society; Thos. B. Van Alstyne, of Albany; Walter J. Ransom, of Lockport; John M. Bigelow, of Albany; A. W. Stein, of New York; W. F. Fulton, of Newark, Wayne Co.; Sheldon Voorhees, of Albany; J. Dunn Lodi, of Seneca Co.; James S. Cooley, of Sandy Hill.

CYSTORRHAGIA.

Dr. J. W. S. Gouley, of New York, then read a paper upon the above subject. It will apear in a subsequent number of the Record.

Dr. Gouley also presented a renal calculus removed from the body of a cow by Dr. C. L. Stiles, of Owego. It was of a zigzag shape, and was supposed to be composed of a mixture of hippurate of soda and phosphates.

PERITYPHLITIS.

Dr. Wm. C. Wey, of Elmira, then read a paper on the above subject, which consisted of the report of a case, and a tabulated statement of fifty-nine cases taken from the Surgeon-General's Office, Washington, D. C. In his case the operation was performed on the fifteenth day. The wound closed, was reopened

the following day, and a drainage-tube inserted, which had been worn 145 days. It was now one and a half inches long, at first being about six inches in length. He favored early operative interference, and regarded it as unwise to delay the exploratory incision in his case to the fifteenth day. From general treatment, the ordinary evidence of the formation of pus may be obscured. The drainage-tube is an essential aid to cure, and should be inserted when the operation is performed. Of the 60 cases, 45 were male, 12 female, and in 3 the sex was not given. The earliest operation was performed on the fifth day, the latest at the end of two years. Foreign body was mentioned in 19 cases; recovery occurred in 44 cases; 12 patients died; result not stated in 3.

Dr. Van Derveer, of Albany, then read a paper on

TYPHLITIS AND PERITYPHLITIS,

which consisted in the relation of cases, with remarks on three cases of perityphlitis. The operative interference gave all the good results that could be desired. All these cases recovered. In typhlitis he suggested opening the abdominal cavity, observing antiseptic precautions in cases where marked symptoms were present.

THE EVIL CONSEQUENCES OF NEGLECTED COLD IN THE HEAD

was the title of a paper read by Dr. D. B. St. John Roosa, of New York. It will be found that the most frequent origin of chronic diseases of the lachrymal passages, of the conjunctiva, and of the middle ear, is in a neglected "cold in the head." It is generally conceded that no person in perfect health, except under extraordinary circumstances, takes cold, and yet the majority of mankind have, at some time, suffered from cold in the head. The popular idea that a cold in the head is an insignificant affair is founded on the fact that most of the people recover to such an extent that they are able to go about afterward and engage in their ordinary avocations without special notice, at the time, of the consequences of the disease which may even then be settled upon them. He believed that very many of the maladies which prevented men and women from reaching the allotted period of threescore and ten have their origin in these colds; and that many serious affections which act as an impediment to the success of their victim are dated from a cold in the head. He then gave a biographical sketch of a child, perhaps feeble when born, or, it may be, in an apparent condition of strength, who became the subject of hypertrophy of the tonsils, swollen naso-pharyngeal mucous membrane, watery eyes, and, worst of all, impaired hearing, perhaps so much impaired that he is not able to hear enough to perform properly the ordinary duties of life. He then described the suffering incident to an acute attack of cold in the head, and of the impossibility of having repeated attacks without producing serious local changes—not only local change, but a permanent impairment of general nutrition. To correct all this, special attention must be paid to *individual* hygiene, and if the evil consequences of neglected cold in the head were to be abolished, the abolition must come through a public sentiment properly educated upon this as upon all other sanitary questions. The family practitioner must warn the people everywhere, as opportunity is offered, of the danger in this direction, and of the means by which it is to be avoided. The first great precaution to be taken by each individual is to keep himself in a good general condition, and to do that he must studiously avoid all that tends to disorder the skin and the functions of all the organs of the body. Children must be clothed in flannel the year round, and must be made to know that the staples of diet are milk, bread, meat, vegetables, and fruit, and that tea and coffee and pastry of all kinds are to be used only as the greatest of luxuries, and therefore in small quantities and at long intervals. The community can only become healthy as individuals become healthy, and all the reforms necessary to make Memphis and Grenada places in which yellow fever never comes, may be adopted; but if control cannot be obtained of the bodies of, and the modes of living of the individuals in those and all other places, evils not so suddenly fatal, but none the less in the end dangerous, and all the time injurious to their well-being, will certainly exist.

It was discussed by Dr. Jacobi, of New York, and Dr. Kneeland, of Onondaga Co.

Dr. L. D. Bulkley, of New York, then read a paper

ON THE MANAGEMENT OF INFANTILE ECZEMA.

The text of his paper was the saying of Wilson: "To be a successful practitioner in eczema the medical man must be an accomplished physician, and to manage the local treatment with success he must be an able surgeon."

This paper was discussed by Dr. A. Jacobi, of New York, who pointed out what he regarded as two errors in the paper. First, a comparison between the secretion from the kidneys and from the breast. In the kidneys there is a real transudation, in the breast there is a real transformation. Fortunately for the young human being, slight changes in the diet of the mother had no influence on breast-milk. Second, the addition of potassium to cow's-milk, for it already contained too much potassium in comparison with breast-milk. Sodium should be added rather than potassium.

Dr. Sherman, of Ogdensburg, thought the eruption should be healed as rapidly as possible.

Dr. E. M. Moore, of Rochester, was not exactly able to understand how, if eczema was a constitutional disease and yielded only to constitutional treatment, that Dr. Bulkley should report cases of cure of eczema by the use of Martin's rubber bandage. How does the rubber bandage cure if eczema is a constitutional disease?

Dr. H. G. Piffard, of New York, thought that not all cases of eczema could be treated alike, and referred somewhat extensively to the indications for treatment in different cases.

Dr. Bulkley remarked that he did not make the reference to urine and milk from the breast as being analogous secretions; but the point was merely that, when urates in excess, oxalates, etc., were found in the urine, it was evidence that the mother's general condition was not good; therefore, her milk was not what it should be.

With regard to the use of the rubber bandage, the cases in which it effected a cure alone were cases of dermatitis, and not true eczema.

The Society then adjourned to meet at 7 P.M.

First Day—Evening Session.

The Society was called to order at 7.20 P.M., by the President.

The first order of business was the report of the Committee on By-Laws, which was made through the Chairman, Dr. Wm. C. Wey, of Elmira. Several amendments were made, the most important of which

was raising the annual dues of permanent members to five dollars, to take effect next year.

Dr. John C. Peters, of New York, then read a paper on the stamping out of

ZYMOTIC DISEASES.

The interest of the paper centred upon thorough disinfection of *all* discharges from the patient sick with any disease belonging to this class, and upon cleanliness, and protection, and disinfection the surface of the body by disinfectant inunction. The Society then adjourned to meet Wednesday, 10 A.M.

WEDNESDAY, FEB. 4TH. SECOND DAY—MORNING SESSION.

The Society was called to order at 10 A.M., by the President.

Prayer was offered by Rev. Edson McChesney.

The minutes of the preceding day were read and approved.

A memoir of Dr. John S. Thorne was presented by Dr. Hasbrouck, and referred to the Committee of Publication.

MEMBERS BY INVITATION.

The Chairman of the Committee of Arrangements announced the following as members by invitation, and they were duly elected:

Drs. Henry Foord, of Canenovia; Anthony P. Ten Eyck, of Defriestsville; R. H. Sabin, of West Troy; Maurice J. Levi, of Albany; T. K. Perry, of Albany; M. H. Turner, of Crown Point, Essex Co.; John C. Hall, of Olmsteadville, Essex Co.; Ezra C. Bartlett, of Albany; Wm. H. Murray, Eugene Van Slyke, and C. S. Merrill, of Albany; H. D. Vosburgh, of Lyons; Franklin Townsend, Jr., of Albany; H. T. Dana, of Cortland; E. W. Carmichael, of Sand Lake; Chas. H. Chubb, of Palensville; E. G. Clark, of Sandy Hill; Harriet A. Woodward, of Albany; Smith Parker, of Whitesboro; E. B. Taft, of Albany; Thomas Riley, of Adams, Mass.; D. M. Wilcox, of Lee, Mass.; John Gerin, of Auburn; E. T. Rulison, of Bath-on-the-Hudson.

TREASURER'S REPORT.

Dr. Chas. H. Porter, of Albany, Treasurer, presented his report, which was accepted and referred to an auditing committee.

A detailed report was made of the receipts and deficiencies in connection with the publication of the Transactions from the year 1874 to the year 1879, inclusive, and one reason for an apparent deficiency for the publication of the Transactions for 1879 arose from the fact that the Medical Society of the County of New York had not yet sent in its order nor paid the amount of its assessment.

Dr. D. B. St. John Roosa, of New York. Mr. President: I wish to make an explanation as showing pretty well the reason why the Medical Society of the County of New York appears this morning as not having ordered its quota of Transactions, and I wish these facts to go upon record. I have no official connection with the Medical Society of the County of New York, but, as a member of the State Medical Society, I was very much interested to find out whether it was true or not that there was no kind of demand for the volumes of Transactions of the Medical Society of the State. I found that the Comitia Minora of that society had agreed upon a resolution, the details of which I cannot remember, but the gist of it was the Medical Society of the County of New York should refuse to take any more volumes of the Transactions, because it was an illegal action to tax them for the books. As soon as I heard of this proposition of the Comitia Minora, I went into the Society, as some of the gentlemen upon this floor will testify, and brought the question to an issue, in the month of October, as to whether or not the Medical Society of the County of New York proposed to pay its assessment and take its volumes of Transactions; and I took opportunity, at the same time, to make the statement that no facilities were given to the members of the County Society to see the Transactions of the State Society. The County Society at that time, by a large vote—the ayes and nayes being called for—decided to pay this amount, and the understanding was that the payment should be made at once; but it has not been done, despite this record, and the Society, through its officers, so far as we know, has declined to order that the amount should be paid, and that in the face of the expressed will of the Society. Then, at a meeting held on the Monday evening preceding this meeting, a resolution was introduced from the Comitia Minora, stating the so-called facts as regards the funds and the legality of the taxation by the State Society, protesting against such assessment; and that resolution was, by an overwhelming vote at a large meeting, laid upon the table, and yet, to my surprise, I come to Albany and find that the Transactions for 1879 have not been ordered, and, worse than that, that they have not been paid for.

The Auditing Committee consisted of Drs. W. W. Porter, H. C. Hendrick, and H. March.

Dr. Chas. H. Porter made a report concerning the Merritt Cash Prize Fund, which was accepted.

On motion made by Dr. J. P. White, of Buffalo, a committee of three was appointed to report upon the resolutions and recommendations of the Treasurer, and to report, if possible, at the present meeting. The committee consisted of Drs. J. P. White, D. B. St. John Roosa, and E. R. Squibb.

Business communications were received from the Secretary, and referred in the usual manner.

Dr. Dimon, of Cayuga County, reported upon the resolution adopted at the annual meeting for 1879, regarding the raising of a roll of honor, upon which should be recorded the names of those who lost their lives in the service of their country or in the discharge of their professional duties. He suggested that the names of those who have made useful discoveries either in medicine or surgery, all such names being referred to the Committee of Examination, should also be added to such a roll.

On motion by Dr. Squibb, the report was accepted and adopted, with the amendment that the words "The Committee" be substituted for the words "The Secretary," and that the committee be continued.

PERMANENT MEMBERSHIP.

Dr. J. V. Kendall introduced the following resolution:

Resolved, That the names of permanent members who are over ——— years of age, and whose names have been dropped from the list because of the non-payment of their annual dues for three years, shall be placed upon the list of honorary members, and shall be restored to permanent membership upon payment of all arrearages.

The resolution was referred to the Committee on Legislation.

MISCELLANEOUS BUSINESS.

Dr. A. Jacobi, of New York, read a communication relating to the *protection of infancy and childhood*, and offered the following resolution:

Resolved, That the President appoint a committee, consisting of *five* members, to co-operate with the Society for the Prevention of Cruelty to Children in all things pertaining to the physical and moral welfare and the safety of infants and children, to report at the next annual meeting.

The resolution was seconded by Dr. Squibb and unanimously adopted, and the President appointed Drs. A. Jacobi, S. O. Vander Poel, E. M. Moore, Jas. P. White, and Joseph C. Hutchison, as such committee.

REFRACTURE IN CORRECTING DEFORMITIES.

Dr. C. C. F. Gay, of Buffalo, read a paper on the above subject, in which he favored the operation strongly, and thought that its neglect had arisen largely from overlooking two important factors: 1. The innocuous nature of refracture; and 2. The certainty and rapidity of the reparative process. He subscribed to the claim that refracture was the most essential in bones of the lower extremities; but greater risks should be taken, in view of greater benefits that might be obtained by refracturing other bones.

Dr. Frank H. Hamilton, of New York, was surprised that the author of the paper had gathered the impression, as he seemed to have done, that surgeons did not advise refracture of vicious limbs, for by so doing, he had put himself in antagonism with the opinion of the majority of the profession upon the subject. The propriety of refracture should *at once* be considered, but *always* in the light of all those circumstances which may endanger a favorable result.

Dr. Robert F. Weir, of New York, then read a paper on "A New Method of Treating Deformities of the Nose," which will appear in a future number of the Record.

"Dr. Thomas Keith and Ovariotomy" was the title of a paper read by Dr. J. Marion Sims, of New York, who said that Keith's great success as an ovariotomist was due to something besides antisepticism, and that he believed it to be "removal of all blood, and making the peritoneal cavity dry and clean before closing the abdominal wound," an application of common sense based upon true principles of science.

Dr. Robert Newman, of New York, referred to a case of ovariotomy in which, in 1866, he divided the pedicle by means of the galvano-cautery knife, and he believed that the heat by that means can be maintained at a more even degree than by any other. In the same case he used *antiseptic treatment* and a drainage-tube, and the patient recovered and is still living.

Dr. W. A. Hall, of Fulton, reported a case of "Uterine Fibroid removed by the Vaginal Method."

"Hyoscyamus in the Treatment of the Insane" was the title of a paper read by Dr. John P. Gray, of Utica. He had used the fluid extract, the solid extract, and the tincture for many years with marked benefit, and also hyoscyamine both by the stomach and hypodermically.

Dr. E. R. Squibb remarked that hyoscyamine was so loosely crystallized that a variety of conditions of the mouth and stomach might readily decompose it by reason of the presence of abnormal secretions, and that fact probably explained why this and other alkaloids, such as pilocarpin, even morphine, administered by the mouth did not produce their physiological effects, whereas, when used hypodermically, the effect produced by the same preparation might be prompt and satisfactory.

The paper was further discussed by Drs. Jewett, Piffard, and Gray.

Dr. A. C. Post, of New York, then read a paper on

CERTAIN UNUSUAL DEFORMITIES OF THE FINGERS AND TOES,

which was discussed by Drs. Frank H. Hamilton, Kneeland, and Robert Newman.

THERAPEUTICAL NOTES.

Dr. A. Jacobi, of New York, under the above heading, referred to the use of *phosphorus in substance* in the formation of new osseous tissue. He also referred to *carbolic acid and oleic acid*, in the proportion of one to eight or ten, and applied to the skin which is tolerably normal around a patch of erysipelas to arrest its further development. Small quantities, frequently repeated, every half-hour or hour, and thoroughly rubbed in with a protected finger. He also spoke of the use of *iodine dissolved in oleic acid* as a local application to the inner surface of the uterus. *Pure quinine* may also be dissolved in *oleic acid* and introduced into the system through the skin.

PAPERS READ BY TITLE.

The following papers were read by title and referred to the Committee of Publication:

"Case of Successful Removal of a Piece of Steel from the Vitreous." By Dr. J. S. Prout, of Brooklyn.

"Report of Delegates to Massachusetts Medical Society." By Dr. P. R. H. Sawyer, of Bedford.

"The Care of the Sick Poor." By Dr. E. Hutchinson, of Utica.

The Society then adjourned to meet at 3 P.M.

SECOND DAY—AFTERNOON SESSION.

The Society was called to order at 3 P.M., by Dr. N. C. Husted, of Tarrytown, Vice-President.

VIVISECTION.

Dr. John C. Dalton presented the subject of vivisection and a memorial addressed to the Legislature of New York, which was unanimously adopted. He also introduced a resolution providing for a special committee, composed of permanent members of the Society, to be known as the Committee on Experimental Medicine, which should be empowered and instructed to take charge of resolutions adopted by the Society in 1867, 1875, and 1880, and present them to the Legislature whenever it was deemed advisable by the committee so to do.

The resolution was adopted and a committee appointed, consisting of Drs. James R. Wood, E. M. Moore, James P. White, Geo. J. Fisher, T. H. Squire, S. O. Vander Poel, Willard Parker, J. C. Hutchison, H. D. Didama, and N. C. Husted.

Dr. Jas. P. White, of Buffalo, introduced the following resolution:

Resolved, That the Committee on Experimental Medicine be empowered to associate with themselves any additional members from State or county medical societies they may desire in order to facilitate the action of the committee, and also to adopt such other measures as they may deem expedient in the discharge of their duties and the furtherance of their work. Adopted.

COLLES'S FRACTURE.

Dr. E. M. Moore, of Rochester, then read a paper on the above subject, which will appear in a future number of the Record. The paper was discussed by Dr. Pilcher, of Brooklyn, on invitation.

ROTARY LATERAL CURVATURE OF THE SPINE AND THE PLASTER-OF-PARIS JACKET.

Dr. Lewis A. Sayre, of New York, introduced a modification in the use of the jacket in the above condition, which was not to remove the *whole of the dressing* and apply a new jacket, but only that which covers the prominent portion of the trunk, cutting out a piece and then adjusting a new portion, which covers and fits snugly to the eminence. The plan was demonstrated.

MODIFICATION OF THE PLASTER-OF-PARIS JACKET.

Dr. Henry Foord, of Cazenovia, exhibited a plaster jacket which he had used in the treatment of a case of Pott's disease, and which was so arranged that *half of the jacket* could be removed while the other remained in position to maintain extension. The jacket was divided on each side, and the sections were held together accurately by clasps made of tin, resembling strap-hinges, and with pins that could be drawn out when the jacket was to be opened. The clasps were placed one near the top and the other near the bottom on each side.

Dr. Sayre thought the idea a very good one, as it apparently sustained extension while the dressing was being changed. It also held the parts together perfectly, and prevented any motion between the cut edges.

MEMBERS BY INVITATION.

Dr. Wm. H. Bailey, Chairman of the Committee of Arrangements, announced the following names as members by invitation, and they were duly elected: Drs. John Thompson, Gideon H. Armsby, G. L. Ulman, Geo. H. Newcomb, of Albany; Chas. S. Allen, of Greenbush; F. L. R. Chapin, of Glenn's Falls; Jas. S. Cooley, of Sandy Hill; Henry Gray, of Greenwich; Meigs Case, of Oneonta; Paul Roach, of Quaker Street; C. W. Hamlin, of Middleville; and Warren Schoonover, of New York.

SUBPERIOSTEAL RESECTION OF THE SHAFT OF THE HUMERUS, WITH REPRODUCTION OF THE BONE.

Dr. Geo. F. Shrady, of New York, read a paper on the above subject, which will appear in a future number of the Record. It was discussed by Drs. A. C. Post and L. A. Sayre.

Dr. Alex. W. Stein, of New York, exhibited a new urethral dilator and speculum. (See Medical Record, vol. xvi., p. 263.)

NEW TREATMENT OF EMPYEMA.

Dr. A. M. Phelps, of Chateaugay, reported a case of acute empyema treated by double puncture: one anterior, as low as possible, into which a tube is introduced; another posterior, into which was introduced a valve drainage-tube, the valve outside. A rubber funnel was attached to the tube in the anterior opening, which was for ablation, and the fluid flowed through, cleansed the cavity, and the valve in the drainage-tube posteriorly prevented the entrance of air.

Dr. F. R. Sturgis, of New York, read a paper on so-called

GALLOPING SYPHILIS,

in which he discussed the causes that render cases liable to run a rapid course, described the symptoms of a typical case, and gave the treatment, which consisted in the use of large doses of iodide of potassium, mercury judiciously exhibited early and late, iodine, tonics, etc. These cases are seen especially among the intemperate, and among persons who have passed the middle period of life.

MERCURIALS IN CONGESTION AND SUBACUTE INFLAMMATION OF THE DUODENUM

was the title of a paper read by Dr. E. M. Chapman, of Brooklyn. It was favorable to their use, and cases were reported.

Dr. Daniel Lewis, of New York, presented

MARSDEN'S TREATMENT OF CANCER,

with a relation of cases. It consists in the use of the arsenious paste, made by uniting *two drachms of arsenious acid* and *one drachm of sanguinaria of gum acacia*, and spread over the entire surface of the cancer, provided it does not exceed one square inch in size. The ease with which it can be used, and the readiness with which patients submitted to the plan of treatment, made it worthy of consideration by the profession.

Dr. W. W. Crandall, of Andover, spoke in favor of the treatment, and Dr. Frank H. Hamilton, of New York, said that he could not admit that it was the most radical method of curing either epithelioma or cancer. Dr. L. D. Bulkley, of New York, remarked that he had the records of twenty cases of epithelioma, in which the method had been adopted, and successfully, with only a single exception.

PAPERS READ BY TITLE.

"Pathology and Anatomy of the Spinal Cord," by Dr. J. C. Shaw, of Brooklyn.

"Memoir to Dr. W. W. Ely," of Rochester.

"Veratrum Viride in Pneumonia and Rheumatism," by Dr. Wm. B. Alley, of Nunda.

A communication from Broome County was referred to the Committee on Legislation.

INJURIOUS EFFECTS OF RETAINED LACHRYMAL SECRETION.

Dr. J. S. Prout, of Brooklyn, spoke upon the above subject, referring to those cases in which the tears are not carried away by the lachrymal canal, and so either causing inflammation, or prolonging that already existing.

The Society then adjourned to meet in the Assembly Chamber at 8 P.M.

SECOND DAY—EVENING SESSION.

THE PRESIDENT'S ANNUAL ADDRESS.

The Society convened in the Assembly Chamber, and at 8.15 P.M., Dr. D. B. St. John Roosa, Ex-President, introduced the President, Dr. H. D. Didama, who delivered the Annual Address, which was brief and suggestive, and was delivered in an easy and entertaining style.

"The opprobria of one age are the accomplished facts of another," was its textual sentence, and, by way of illustration, reference was made to ovariotomy, which, performed first by McDowell in 1809, fell into such disrepute that no longer than thirty years ago it was characterized by distinguished members of the profession as an operation not fit to be made.

Even so late as 1857, Velpeau, in the name of French surgery, denounced it as a venturesome proceeding, and, still later, Scanzoni asserted that the

operation was inexcusable under any circumstances, and that the surgeon who performed it was the guilty instrument of suicide. To-day ovariotomy is universally acknowledged to be one of the most beneficent of the great surgical achievements.

The speaker then referred to the progress which has been made, as illustrated by the advanced methods of treating vesico-vaginal fistula, cataract, morbus coxarius, and in the use of antiseptics in surgery.

But, much as had been accomplished in the recent past, the medical profession is not compelled to shed bitter tears because there are no new worlds to conquer. There are incentives to the noblest ambition and deepest research in the abundance of work still remaining undone—still clamoring to be done. Reference was then made to the signal progress which has been made in medicine, as illustrated by the fact that, with regard to some diseases, we are now familiar with their natural history, and know them to be self-limited. But, notwithstanding the marked progress, such as encountered in Jenner's great discovery in the last century, and many others of much more recent origin, fatal epidemics of disease are not infrequent. It still continues that one-half of the human race die in infancy and in early childhood.

There are many diseases, as Bright's disease, which are sufficiently common to give opportunity for full investigation, and yet, so far as we know, are still incurable. Measles, scarlet fever, and other fevers, run their accustomed course, modified, perhaps, by progressive medicine, yet not cut short a single hour. Must this remain so? Must our aspirations, and hopes, and efforts, be paralyzed by the dictum of authority? "Thus far canst thou go, but no farther." It is but a brief period since it was held and taught, by the illuminate of the profession, that Asiatic cholera arose without known cause, and spread mysteriously, subject neither to therapeutical restraint nor sanitary law; that small-pox originated from filth and bad air, and even fear alone. Many diseases, whose origin was once unknown, are now acknowledged to be due to specific morbid elements, capable of producing its own kind and none other, and also capable of indefinite multiplication. The President then dwelt at some length upon the germ theory, which, although not universally accepted, accounted as no other hypothesis does for the incubation of eruptive and other fevers, even the malarial.

He then passed to the consideration of a State board of health, to be composed of the most learned, prudent, practical, and energetic sanitarians in the land, to whom should be given plenary power as a means for dissipating prevailing ignorance, rousing the people from their dangerous apathy, and compelling the accomplishment of incalculable good. It would be the duty of this board to instruct the laity, and the profession as well, concerning ventilation, drainage, sewerage, foods and drink, pointing out that the germs of many deadly diseases, while never produced by filth, are often transplanted to it, that they breed and flourish in it, and are disseminated by it. It should be the further duty of this board to teach that zymotic diseases are preventable and should be abolished, and to impress upon the people that the continuance of these diseases should imply not ignorance alone, but criminal negligence. Reference was then made to the effects of a few zealous specialists in opposing and seeking to prevent by legislative enactments all experimentation on living animals, however carefully and painlessly conducted the investigation may be, and however wisely designed to advance that science which relieves human suffering and prolongs human life—as if the humblest of us were not of more value than many sparrows—notwithstanding the undoubted benefit that has accrued to the human race from vaccination, and many other agents to which we have been helped by the aid of the lower animals.

The President then spoke of the difficulties laid in the way of advancing science and of the reforms necessary, and urged his hearers and fellow-workers to labor with patience and perseverance for the grand results that were inevitable in the future. He suggested a more careful and practical course of instruction for medical students, and argued that the manner in which the rising generation of physicians were to be trained for their future work was of great importance to the future welfare of the people. The medical schools should recognize the need of better methods and a more thorough culture. The plan which he suggested, although it might not be the best, was one which afforded a fair foundation for a system of better medical education. It was substantially as follows:

1. All persons wishing to enter a medical school must have, as the minimum, such qualifications as are required for admission into any literary college in the nation.
2. A complete graded system.
3. The course of instruction extended to at least three years of nine months each.
4. Constant attendance upon lectures; oral examinations weekly, and written ones monthly, required of every student.
5. Anatomical, chemical, histological, and pathological work compulsory.
6. Satisfactory examinations preceding advancement in grade.
7. Final examination conducted by an independent board appointed by the Regents of the University.

The benefits arising from the adoption of such a plan were then pointed out, and dwelling upon the future possibilities, he closed by saying: "However anxious I may be that needed reforms should take place speedily, I am not discouraged at the slow progress which fruitful truth makes in permeating the masses of men, for she has 'the eternal years of God' before her; neither am I doubtful of that final triumph of sanitary, medical, and religious science, when 'there shall be no more an infant of days, for the child shall die an hundred years old,' and when the hoary head shall always be a crown of glory, because always found in the way of righteousness."

The address was listened to with marked attention, and at its close Dr. John P. Gray, of Utica, moved that the thanks of the Society be tendered to the President for his able and interesting address, and that a copy be requested for publication in the volume of Transactions. The motion was seconded by Dr. Wm. C. Wey, of Elmira, and unanimously adopted.

The Vice-President, Dr. N. C. Husted, then declared the Society adjourned to meet at nine o'clock on Thursday morning.

The annual banquet was held at the Delavan House immediately after the President's address, and in all respects was pleasant and satisfactory. Toasts were responded to by Drs. D. B. St. John Roosa, Alex. Hutchins, Lewis A. Sayre, John C. Dalton, Wm. C. Wey, Frank H. Hamilton, and Mr. Wm. H. Bogart. Responses were made, upon call, by Dr. E. M. Moore, Mr. McKelway, and Dr. Wm. H. Bailey.

THURSDAY, FEB. 5TH.—THIRD DAY.—FINAL SESSION.

The Society was called to order at 9.15 A.M., by the President.

Prayer was offered by REV. J. LIVINGSTON REESE.

The minutes of the previous day were read and approved.

MEMBERS BY INVITATION.

DR. BAILEY, Chairman of the Committee of Arrangements, proposed the following gentlemen as members by invitation: Drs. George W. Papen, Thomas M. Trego, Willis G. Tucker, Jas. P. Boyd, Jr., P. B. Collier, of Albany, and H. F. Ketchum, of Cambridge.

The Committee of Publication made a report, which was accepted.

The report of the special committee upon the medical act contained in the new proposed revised statute was read by DR. H. G. PIFFARD, of New York, Chairman, and referred to the executive officers of the Society, with power.

DR. H. G. DU BOIS, of Oneida County, made a report as delegate to the Michigan State Medical Society.

REPORT OF CENSORS.

The censors of the *first* district made a report and offered the following resolution:

"*Resolved*, That the censors of the Society be instructed to use the greatest caution in recommending candidates for licenses to practise medicine and surgery, and that only after a rigid examination at a higher standard than that required to graduate from any medical college in the land."

The resolution was adopted.

The Business Committee reported a communication from an aggrieved member of the profession of the County of Monroe, which was referred to the Committee on Medical Ethics.

DR. E. R. SQUIBB, of the committee appointed to report upon the recommendations contained in the treasurer's report, reported in favor of a more free distribution of the Transactions of the Society in the discretion of the officers of the Society, and that volumes for past years be sold at $1.50 per volume. The committee also recommended the publication of an edition of 1,200 copies of this year's Transactions, upon the same conditions as last year.

The report was accepted and the recommendations adopted.

The Auditing Committee reported that they had examined the accounts of the treasurer, and had found them correct in every particular. Accepted.

The Business Committee presented a memorial from the Greene County Medical Society, which was referred to the Committee on Ethics.

THREE CASES OF PUNCTURING GUNSHOT WOUNDS OF THE THORAX

were then reported by DR. JAMES CHAPMAN, of Medina. Two of the cases proved fatal.

DR. F. C. CURTIS, of Albany, made

SUGGESTIONS REGARDING IMPARTIALITY IN THE EXAMINATION OF CANDIDATES FOR DIPLOMAS.

The profession, as a matter of self-protection, has a right to say what the qualifications shall be of those who seek entrance into it. He recommended that medical schools be requested to resign their chartered right to confer degrees in medicine, and vest that right in the Board of Regents constituting the University of New York.

DR. E. D. FERGUSON, of Troy, reported a case of

DIAPHRAGMATIC HERNIA.

DR. J. VEDDER, of Saugerties, read a paper

ON HYGIENE.

It was discussed by DR. E. M. MOORE, of Rochester, who spoke of the great difficulty in getting municipal authorities to recognize the necessity of sanitation; by DR. B. F. SHERMAN, whose experience had been somewhat similar to Dr. Moore's in that particular; by DR. I. N. GOFF, who believed that, if the people were properly educated, there would be no difficulty in getting them to respond by money or otherwise for that which is necessary to promote either the health of the children in the public schools, or the health of the people in general; by DR. JOHN SWINBURNE, who spoke of ventilation by means of frames covered with thin, unstarched muslin, to take the place of the whole, or part, of the upper or lower half of the window.

A paper from DR. A. N. BELL, of Garden City, was read by title, and referred to the Committee on Hygiene.

REPORT OF THE COMMITTEE ON THE PRESIDENT'S INAUGURAL ADDRESS.

DR. E. M. MOORE, Chairman, reported that the committee agreed that the examination of students, for the degree of doctor in medicine, by an independent body, would be a gain over the present method. The difficulties, however, in constructing such a board, were very great.

With regard to the recommendation that a law should be sought making provisions that the plaintiff shall give bail for costs in suits of malpractice, the committee could only say that, while such legislation may be desirable, they do not feel justified in offering any opinion upon a question which requires legal knowledge.

THE TREATMENT OF VASCULAR NÆVUS.

DR. G. H. FOX, of New York, read a paper on the above subject, which was discussed by Drs. Sherwell of Brooklyn, and Bulkley of New York.

The following papers were read by title, and referred to the Committee of Publications: a paper relating to "Lunacy Reform," by Dr. Allan McLane Hamilton, of New York; "Domestic Pestilence," by Dr. Elisha Harris, of New York.

REPORT OF THE COMMITTEE ON NOMINATIONS.

The Committee on Nominations, DR. S. O. VANDER POEL, Chairman, submitted the following nominations as the unanimous action of the committee:

For President.—Dr. Wm. H. Bailey, of Albany.

For Vice-President.—Dr. A. Jacobi, of New York.

For Secretary.—Dr. Wm. Manlius Smith, of Manlius.

For Treasurer.—Dr. C. H. Porter, of Albany.

For Censors.—Southern District: Drs. J. W. S. Gouley, C. R. Agnew, and Austin Flint, of New York.

Eastern District: Drs. Ed. D. Ferguson, M. H. Burton, and W. S. Cooper, of Troy.

Middle District: Drs. Alonzo Churchill, S. G. Wolcott, and J. K. Chamberlayne, of Utica.

Western District: Drs. Thos. F. Rochester and Henry Lapp, of Buffalo.

Committee of Ethics.—Drs. Thos. Hun of Albany, E. M. Moore of Rochester, and C. R. Agnew of New York.

Committee of Publication.—Drs. Wm. Manlius Smith, H. D. Didama, of Syracuse, and Chas. H. Porter, Albany.

Committee on By-Laws.—Drs. Wm. C. Wey of Elmira, Alex. Hutchins, of Brooklyn, and C. A. Robertson of Albany.

Committee of Arrangements.—Drs. S. B. Ward, F. C. Curtis, and J. S. Mosher, of Albany.

Committee on Prize Essays.—Drs. E. M. Moore of Rochester, T. F. Rochester of Buffalo, and W. S. Ely of Rochester.

Committee on Hygiene.—Drs. E. V. Stoddard of Rochester, D. Guernsey of Amenia, Jacob S. Mosher of Albany, J. G. Orton of Binghamton, C. R. Agnew of New York, E. Hutchinson of Utica, and Harvey Jewett of Canandaigua.

Committee on Legislation.—Drs. H. G. Piffard of New York, Alex. Hutchins of Brooklyn, and A. VanDerveer of Albany.

Permanent Members.—First District: Drs. C. Henry King of Richmond Co., R. M. Wycoff of Kings Co., and H. G. Piffard, R. F. Weir, and H. Knapp, of New York Co.

Second District: Drs. R. K. Tuthill of Dutchess Co., and J. O. Polhemus of Rockland Co.

Third District: Drs. D. V. O'Leary of Albany Co., and F. S. Greene of Clinton Co.

Fourth District: Drs. P. R. Furbeck of Fulton Co., and E. M. Lyon of Clinton Co.

Fifth District: Dr. Ira H. Abell of Jefferson Co.

Sixth District: Drs. C. H. Heaton of Tioga Co., and H. R. Ainsworth of Steuben Co.

Seventh Dist.: Dr. M. D. Benedict of Onondaga Co.

Eighth District.—Drs. Jabez Allen, of Erie Co., and E. V. Stoddard, of Monroe Co.

Honorary Members.—Drs. John S. Billings, U. S. A.; Joseph B. Brown, U. S. A.; and W. F. Teevan, F.R.C.S., London, Eng.

Eligible to Honorary Membership.—Drs. Wm. Farr, of London, Eng.; T. J. Turner, U. S. N.; and Dr. Walter Carpenter, of Burlington, Vt.

DELEGATES.

To the Massachusetts Medical Society.—Drs. A. Van Derveer, of Albany Co.; J. V. Kendall, of Onondaga Co.; and Lewis H. White, of Dutchess Co.

To the Medical Society of the State of New Jersey.—Drs. J. C. Hutchinson, of Kings Co.; S. O. Vander Poel, of Albany Co.; R. Newman, of New York.

To the Vermont State Medical Society.—Drs. H. B. Allen, and D. S. Kellogg, of Onondaga Co., and G. C. Dodge, of Clinton Co.

To the Indiana Medical Society.—Dr. J. S. Bailey, of Albany.

To the Kansas State Medical Society.—Dr. Conant Sawyer, of Essex Co.

To the American Medical Association.—Drs. D. B. St. John Roosa, J. W. S. Gouley, John H. Hinton, of New York; J. C. Hutchison, of Brooklyn; C. C. F. Gay, of Buffalo; E. M. Lyon, of Clinton Co.; Theo. Dimon, of Cayuga Co.; J. V. Kendall, of Onondaga Co.; P. R. H. Sawyer, of Westchester Co.; W. Govan, of Rockland Co.; E. R. Squibb, of Brooklyn; E. D. Ferguson, of Troy; N. L. Snow, of Albany; C. S. Nichols, of Troy; B. F. Sherman, of St. Lawrence Co.; E. H. Parker, of Dutchess Co.; J. M. Bigelow, of Albany; H. R. Ainsworth, of Steuben Co.; C. H. Heaton, of Tioga Co.; T. B. Reynolds; H. S. Crandall, of Madison Co.; Darwin Colvin, of Wayne Co.; J. Kneeland, A. J. Dallas, and J. S. Dunlap, of Onondaga Co.; H. C. Hendricks, of Cortland Co.; William Oliver, of Yates Co.; Isaac Parsons, of Onondaga Co.; and H. N. Porter, of Oneida Co.

The President and Secretary were empowered to fill all vacancies.

All the officers were elected by an affirmative ballot cast by the Secretary.

Dr. L. D. Bulkley, of New York, introduced a plan by which the business of the Society could be largely transacted, and thus save the time for scientific purposes. It was referred to the Committee on By-Laws.

Dr J. V. Kendall, of Onondaga Co., moved that the thanks of the Society be tendered to the retiring President for the gentlemanly, impartial, and faithful manner in which he had discharged his duties as its presiding officer. It was unanimously carried.

The retiring President returned his thanks to the Society for the personal compliment, for the uniform courtesy extended to him throughout the meeting, and congratulated the Society upon the good work done.

The Society then adjourned to meet in the city of Albany on the first Tuesday in February, 1881.

Correspondence.

HIGH TEMPERATURE IN ACUTE PNEUMONIA—105°–110° F.—RECOVERY.

To the Editor of The Medical Record.

Sir:—I was called to visit Miss Laudengrauer, æt. 17 years, of stout build, light complexion, flaxen hair, lymphatic temperament, on evening of December 16th ult.

The thermometer registrations were as follows:

Dec. 16th.—9 P.M., 101½°.

(I will here state that I used several times two reliable thermometers, which perfectly agreed.

Dec. 17th.—11 A.M., 102°.

Dec. 18th.—Patient was neither visited nor reported.

Dec. 19th.—Messenger reported case at office, and medicine was sent.

Dec. 20th.—Called at 12.30 P.M. Patient worse in every respect; temperature, 105°; 8 P.M., 103°.

Dec. 21st.—9 A.M., temperature, 105°; 12 M., 110°; 4 P.M., 105°; 9 P.M., 103⅓°.

Dec. 22d.—Six A.M., 101°; 10 A.M., 100°; 1 P.M., 106°; 8 P.M., 101½°.

After this time, and until recovery was complete and my visits and examinations ceased, the temperature ranged from 96° to 100°, most of the time during convalescence being below 98°. The lung-tissue involved was the lower and middle lobes of the right lung.

The pulse once or twice, and for short periods during the most acute stage and suffering, ran as high as 150, and fell in convalescence as low as 56 per minute. Remedies used in course of the treatment were briefly as follows, viz.: hot or very warm wet flannels locally over seat of pain for first forty-eight hours (commenced by the nurse before I was called), improved comp. cath. pills, two, followed by Rochelle salts. The latter was repeated at various times through whole course of the treatment, in either cathartic or aperient doses, as seemingly indicated. Bromide of potassium was used in doses of gr. v.–x., number of doses per diem varying from two to eight, according to the cough and restlessness. Bicarb. sodæ was combined in solution with it when urine was scanty, or none voided for hours (diuretic doses). Sugar and calomel was given (sacch. alba, gr. x.; calomel, gr. i., triturated) on the sixth,

seventh, and eighth days; amount of bilious vomiting and high fever, followed by small loss of blood.

Cinchonidia sulphat was used during the whole treatment at intervals of from two to five hours, and in doses varying from gr. iij–viij. A few ordinary opiate doses were given during the course of the case, when the pain was too severe; sometimes the pulv. Dover, and sometimes the morphiæ sulphat, shortest interval of these doses being twenty-four hours.

Five doses of tr. gelsemii (W. S. Merrell's green root preparation) were given, the first, gtts. viij, on the sixth day, second dose, gtts. xvj, at 9 A.M., when temperature stood 105°, and in three hours thereafter, 12 M., had risen to 106°, 4 P.M., fallen to 105°, 9 P.M., 104°. At this latter named hour patient seemed fairly at the crisis, and under full influence of the gelsemium, short of toxic effect as described by Bartholow's Mat. Med.

Respiration slower than normal, showing partial paralysis of respiratory muscles, and patient prostrate, in very profuse perspiration. Patient also took of spirits turpentine, on sugar, gtts. xv. (single dose), on tenth day of illness, on account of the dry typhoid tongue and mouth. Water was given freely, as patient would, or desired to drink, at all times. For four or five days, during the height of disease or acute stage, scarcely any food was or could be taken. Milk was given freely when it could be taken, patient had a great dislike to its taste, although she took, on an average, two glassfuls per day after the seventh day of treatment. First craving, or appetite, at commencing improvement, was for oranges, which were allowed, and eaten ad libitum. Patient was often sponged with salt water of agreeable temperature during the periods of high fever. No urine was voided for eighteen hours after the administration of the second and last dose of *gesemium*. The catheter, however, was not demanded, bladder not becoming distended; the kidneys at fault or not secreting, soon and gradually resumed their function. Made my last visit and prescription to patient on 28th ult. She at this writing is dismissed from treatment and able to be about house in family circle.

Allow me to remark in conclusion, that, had I used the cold bath or wet pack in this case, I undoubtedly would have attributed the recovery to it. And further, that at every opportunity for the past eight years I have used the clinical treatment, and never before nor since have I seen it register 110, and 105 (except in intermittents) has always given me great concern, if not alarm. I once saw 107½ in a case of *pneumonia*, the patient dying within two hours thereafter.

W. Scott Marshall, M.D.

Locust Street Centralia, Ill.

UNPROFESSIONAL CONDUCT ON THE PART OF ATTACHES OF DISPENSARIES AND HOSPITAL OUT-DEPARTMENTS — A TRUE "DISPENSARY ABUSE."

To the Editor of The Medical Record.

Dear Sir:—There has been a great deal said and written about dispensary abuses, and I have come to the conclusion that they are not a myth; but I also believe that for the most flagrant abuses of this nature the medical attachés of the dispensaries and hospital out-departments are largely responsible.

Apart from the injustice of giving free advice to those well able to pay for it, and about which much has been said, there is a much more reprehensible practice sometimes indulged in at these institutions. I refer to the tone of censure, either direct or indirect, with which the previous treatment of patients seeking advice at them is too often commented upon. It not infrequently happens that patients leave these temples of wisdom and infallibility with the idea that their outside medical attendant has done them great injury. This is especially the case at those places where patients seek the aid of specialists, who, although often young and little experienced in their departments, are very apt to assume a sort of censorship over the outside medical public. Even if a patient seeking advice at a dispensary or clinic may not have previously received proper treatment, it is not proper, nor within the province of the attending physician or surgeon, to pass judgment upon it. He has simply to examine, make a careful diagnosis, and, if possible, cure his patient, without comment upon previous treatment.

What shall we say, then, when such an attendant not only directly censures the previous medical adviser of a patient, but at the same time, in acting upon his own opinion, commits an error which only the grossest carelessness or dearest ignorance could have rendered possible? The facts of the case which has led me to make these remarks are briefly as follows:

About the 17th of November last a married woman, in good general health, the mother of two children living, and two dead, and who had borne a child eighteen months before, was induced by a friend to seek advice at the out-department of one of our hospitals. She had passed two menstrual periods, and was nearing the third. She had never been irregular before, except when pregnant, and suffered now from leucorrhœa and an unpleasant pressure upon the rectum and bladder. Upon presenting herself, she gave to the attending physician the above history, and stated that she desired first of all to know whether or not she was pregnant, and, if not, to be treated for her symptoms. The physician made an examination, and told her that she was not pregnant, but that the womb was large and soft; that she was suffering from uterine catarrh; that this was the result of bad treatment after confinement, and that the cervix had been lacerated. He recommended hot injections, gave a prescription, and directed the patient to return in a week.

This examination was followed by some hemorrhage, and when the patient returned in two weeks, on December 1st, no further examination was made, but the patient was directed to continue the injections. A third visit was made on December 8th, when a second examination was made. After this examination, the physician reiterated his statement about the condition of the uterus, and stated that energetic treatment would be necessary to reduce its size—it now measuring, according to his description, six or eight inches in depth. He said that for efficient treatment it would be necessary for her to enter the hospital, and remain for some time. He did not suspect, evidently, how efficient the treatment he had already begun would soon prove in speedily "reducing the size of the womb one-half." It did not seem to occur to him that a much enlarged and soft uterus, in a healthy married woman who had not menstruated for three months, in connection, too, with leucorrhœa, meant, or *might* mean, pregnancy. He recommended, in lieu of her entering the hospital, that her physician (acting upon his superior suggestion) should frequently wash out the uterine

cavity. Am I wrong in inferring, in view of all this, that before arriving at this very exact diagnosis he must have explored the uterine cavity? And am I wrong in claiming that the flowing which began after the first examination, and which was followed on the 19th of December by the expulsion of a fœtus of three or four months, was due to either great ignorance or still greater carelessness? Let me briefly state that this was followed by a most violent rigor, during and after which the temperature rose to 105°, and it was only after the greatest and most persevering effort that I succeeded in removing a well-formed placenta.

The woman was in great danger, and only after her partial recovery did she make me aware of the facts above stated. Let me conclude by stating that the patient was in no sense a proper one for treatment at the institution she sought, as could have been easily ascertained upon inquiry, her husband being quite able and willing to pay his physician. Let me also say that, though I have often felt aggrieved at matters similar to the above, but of not so serious a nature, I have hitherto refrained from making them public, partly out of a desire to avoid hurting any one's feelings, and partly from that instinctive avoidance of unpleasant matters which most of us feel. This same feeling now induces me to withhold the name of the physician who, while carelessly or ignorantly imperilling his patient's life, did not hesitate to cast a slur upon a colleague; and leads me to conceal the name of the hospital to which he is attached.

S. Seabury Jones, M.D.

809 Lexington Avenue.

TRANSFUSION WITH DEFIBRINATED BLOOD.

To the Editor of The Medical Record.

Sir:—The interest awakened by the successful employment of defibrinated blood, *per rectum*, as a valuable auxiliary in the treatment of disease, leads me to call attention to the experiments of Prof. Ponfick,* which have not been recorded, to my knowledge, in any of our journals, and which seem to open a new sphere of usefulness for this agent. I allude to the intra-peritoneal injections of defibrinated blood, which Prof. Ponfick ranks as a simple and effective method of transfusion, devoid of the difficulties and dangers attending the ordinary procedure of transferring the blood directly from one person to another.

For some years back Prof. Ponfick, by way of experiment, had been injecting defibrinated blood into the peritoneal cavity of dogs, and noticed that the reaction following was hardly perceptible, while the absorption of the injected fluid was exceedingly rapid. Encouraged by these uniformly favorable results, he has lately employed this novel method of transfusion in three patients with perfect success, the only phenomena following the operation being a slight febrile movement and abdominal pain, both of very short duration. The quantity injected was 250 grammes in the first case, 350 in the second, and 220 in the third patient, and Prof. P. thinks that a larger quantity of blood can be introduced without any strain on the heart, lungs, or brain, owing to the gradual manner in which the absorption of the defibrinated blood is effected.

The apparatus employed is identical with that used by Prof. Thomas for intra-venous injection of milk, and the whole procedure consists in the introduction of the canula through the abdominal walls into the peritoneal cavity, and then allowing the required quantity of blood to flow in.

Should further experience with a larger number of cases be productive of the same happy results obtained by Ponfick, and the direct entrance of the injected blood into the circulation be established by ascertaining the quantity of red corpuscles in the patient's blood before and after the injection, this simple method of transfusion, requiring only ordinary skill for its performance, can be applied to many others than extreme and desperate cases, and defibrinated blood will fulfil an indication not second in importance to that of supplementary rectal alimentation, which, until now, it has so admirably served.

"VALVULAR DISEASE OF THE HEART."

Spasms in a Moribund Patient.

To the Editor of The Medical Record.

Sir:—In a recent issue of the Record, p. 88, Dr. Talbot Jones details a very interesting case of valvular disease of the heart, which presented this peculiar feature, that in a "moribund" patient with a feebly beating heart, failing circulation, and rapidly approaching dissolution, muscular spasms and convulsive movements occurred, so that "the elbow was raised from the bed, the leg was drawn up with considerable force;" the muscles of the face also exhibited "violent and fitful contractions." These spasms "recurred at intervals of three or four seconds," and resembled "the twitchings which would be produced by a galvanic current."

Dr. Jones is at a loss how to account for "these remarkable phenomena" under the circumstances, and finds the usual "possible explanations" unsatisfactory. In response to his inquiries, I beg to submit the following facts, which, I think, afford the necessary explanation of the situation.

Sir Astley Cooper has shown (Guy's Hospital Reports) that if the basal ganglia of the brain be deprived of their normal supply of blood, as by compressing the vertebral arteries, spasms and convulsions speedily occur. Kussmaul and Tenner also have shown, by numerous and interesting experiments, that so far from "a determination of blood to the head" being associated with convulsions, the very opposite is the case; and that defective blood-supply, and a consequent failure of functional activity on the part of the intracranial centres, are really the conditions which occasion spasms and twitches of the muscles.

Are not these the very conditions of the cranial circulation present in Dr. Jones's patient, brought about, not indeed by pressure on the vertebrals, but by failure of the heart, which had long been the seat of valvular disease?

The train of results would be as follows: Undue exertion at play, by causing unusual demand for blood-supply to the limbs and muscles, overtaxed the enfeebled heart, the "violent palpitation" of which was but the effort of a defective pump to propel at several strokes the blood it should have discharged at one.

Notwithstanding this increased effort and the heart's

apparent excitement (in reality defective power), blood does not reach the cranial centres in sufficient quantity to maintain the normal discharge of nerve-force (for it is a physiological law that the activity of an organ is dependent upon its receiving a due supply of arterial blood).—Dr C. B. Radcliffe). As a result, the respiratory centre is enfeebled, respiration is hindered, and cyanosis produced. There are giddiness and coma from defective power of corresponding centres. Among other functions of the medulla oblongata, vaso motor innervation is impaired, and the *dilating* power of the vaso motor nerves over the arterial muscle is withdrawn, permitting the gradual contraction of the calibre of the arterials, which is complete in death. As a result, more blood is excluded from the nervous centres, enfeebling them still more; the dyspnœa increases, and is probably not only aggravated by the failing power of the respiratory centre, but by the contraction of the pulmonary arterioles, the effort to overcome which leads to increased effort and further embarrassment to the laboring heart. Thus, there is not only defective blood-supply, but imperfectly oxygenated blood, reaching the motor nerve centres—two conditions quite incompatible with increased functional activity on their part, and obviously tending rather toward cessation of function.

During the process just described, it would be folly to suppose that the intra-cranial motor centres could be generating and discharging increased nerve-force, wherewith to "stimulate" the muscles to spasmodic contraction. On the contrary, motor nerve-force, as well as vital force, generally is in abeyance; and as the real function of the motor nerves is to *restrain muscular contraction*, this restraint being withdrawn, the muscles contract proportionately to their freedom, from their own inherent contractile power (as do in like manner the muscles of the arterial coats when freed from the domination of their vaso-motor nerves.) Hence the spasmodic muscular movements.

This is not the popular doctrine of the day. But it is in strict accord with the results of the physiological experimentation of Sir A. Cooper, Drs. Kussmaul and Tenner, Dr. Brown-Séquard, and others. Dr. C. B. Radcliffe, F.R.S., deduces from these experiments the proposition that "there is reason to believe that the power of muscular contraction is inversely related to the amount of nervous influence supplied to the muscles from the great nerve-centres." (Lec. on Epilepsy, etc., p. 100.) In other words, that muscular spasm and convulsion are prone to occur in proportion as motor nerve influence is withdrawn, as is seen in death from hemorrhage in certain cases of narcotic poisoning, and in such cases of exhaustion and dying as that under consideration. The doctrine is further strongly supported by the fact that our chief "antispasmodics" are stimulants to nerve-force, and that "stimulants" are the class of drugs which have proved most effectual in the spasm of tetanus.—(Dr. W. A. Hammond, Dis. Nerv. Syst., p. 541.) Such treatment would be preposterous on any other view of the case than that nerve-force is here enfeebled, and that the result is to enable the motor nerves more effectually to restrain the muscles.

But, if the foregoing views are correct, it may be asked why spasms and convulsions are not invariably the precursors of death? Because motor nerve-force is not necessarily extinguished in ordinary modes of dying, and usually even survives the somatic death of the body, restraining muscular contraction for a time, and when finally extinct—usually in a few hours—the muscles pass into rigor mortis, the inherent contractile power with which they are endowed yielding only to the molecular change of putrefaction. The reader must admit that motor nerve-force survives the general death of the body, in order to explain the very numerous and well authenticated cases of post mortem muscular contraction now on record.) See previous issues of the MEDICAL RECORD for September 13, October 25, November 1, December 13, 1879, and the writer's "Physiological Therapeutics," for further references to the views expressed in the foregoing.

I quite agree with Dr. Jones that the condition of his patient was incompatible with "exaggerated motor disturbance," and I believe that in defective blood-supply to the brain, with a consequent deficient innervation, failure of motor nerve-power, and freedom of the muscles to pass into a state of spasm—tonic or clonic in proportion to their freedom—will be found the true physiological explanation of the symptoms peculiar to his case.

Why the convulsive movements were limited to one side of the body, is a secondary issue the explanation of which is to be sought in local modifications of cranial circulation or innervation, and the subject is too obscure, in the absence of further data, for any attempt at elucidation.

Yours, etc.,

THOMAS W. POOLE, M.D.

LINDSAY (ONT.) CANADA, Feb. 2, 1880.

A SUPERIOR QUALITY OF GREEN SOAP, "SAPO OLIVÆ PREPARATUS."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In the local treatment of certain chronic skin affections the value of the German *sapo viridis*, or "green soap," is too well-known to require comment. It has become extremely popular in this country, and there are few unofficinal remedies which are so extensively used. This widespread popularity is due solely to its therapeutic efficacy, and exists despite numerous objections to it which might be raised. Though purporting to be composed of potassa and olive-oil, it is commonly made, as many are aware, of hemp-seed, rape-seed, whale and other animal oils not always free from rancidity. Hence the offensive odor of the green soap which is commonly obtained in the market. The saponification of the soap is not always perfect, and it usually presents a streaky, variegated appearance. Its green color is artificial and due to the presence of indigo and other dyestuffs. It tends to harden on exposure to the air, and finally its alkalinity varies to such a degree as to render its effects more or less uncertain.

Some time ago my friend, Dr. Wm. K. Newton, suggested to me the use of a substitute in the shape of a soft olive soap used extensively in the manufacture of silk and other delicate fabrics. This I have tried and found to be a similar, though a far more elegant article than the ordinary sapo viridis. It is made from cold-pressed olive-oil, and owes its green color entirely to the chlorophyl of the olive. As manufactured by Mr. Bagoe, Pharmacist, of New York, it is of unvarying alkalinity, wholly free from unpleasant odor, homogeneous, and, unlike the common green soap, it gives a perfectly clear solution with strong or dilute alcohol. I have found it advantageous to add to the soap a small percentage of glycerine, which, while counterbalancing the natural

loss of free water, renders it a most agreeable preparation.

Hoping that your readers may derive benefit from the above suggestion,

I am very truly yours,

GEO. HENRY FOX, M.D.

NEW YORK.

"THE PINE RIDGE PRACTITIONER."

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Few articles, not strictly scientific, have had a place in your well-filled columns, which have elicited more interest and attention than the exquisite satire of the Pine Ridge Doctor and the communications which followed those of the "Successful Practitioner." While it is true that one critical correspondent of your excellent contemporary, the *Boston Medical and Surgical Journal*, was somewhat slow in discerning the point, I imagine that his vision was quite unobstructed after he read the letter of his appreciative fellow-contributor from Pau, France.

There can be little risk in predicting that the "Pine Ridge Practitioner" will hereafter be one of the fixed terms of our nomenclature, and that appellation will doubtless cling to many successful practitioners in many parts of the world, who practise "under the code." But the Hudson is not the only stream which has upon its banks such enterprising and conscientious practitioners. In proof of this statement, I will give some extracts from a volume in my library,* which I reread after "the experiences" were detailed in your pages. The author of this work lived in this city, and even at this day there could doubtless be found some in this portion of the world who follow the plan of the author and practitioner writing from Pine Ridge on the Hudson.

Our author addresses a letter to a young medical friend just entering practice, and regrets that while all the medical colleges have a lecturer upon the eye, the throat, the skin, and even upon the ear, there is not one whose duty it is to teach the noble art of getting practice. He then gives the following hints and suggestions to supplement the instructions his young friend has received:

"One of the common stock ways among the pushing fellows of the cities nowadays is to be in league with certain newspapers, and, too, by skilful management, frequently have their names in their local and personal columns; for instance, if you were called to an accident, you would manage to get it into the next day's paper, have it reported how the very skilful and popular Dr. J. Charlatan Greene was called in, and how much he seemed to sympathize with the poor sufferer, and with what skill he dressed the wounds, and what he said about the case, and here, if you throw in as many high-sounding technical phrases as possible, it will tell, for the less the public understand them, the more credit will they give you for wisdom and learning,

> 'For the dull world most honors pay to those,
> Who on their understandings most impose.'

But in the whirl and turmoil of a great city, once will not do to be spoken of, but keep your name before the public until, like that of Helmbold, John Bull, and other . . . . advertisers, the people will at last get it imprinted on their minds simply for the much seeing of it. I have known an instance or two where doctors were supposed to have driven over children in the streets in order to get their names in the papers in connection with the accident. I have heard it said of one very sharp fellow, that when his name had been too long absent from the public gaze, as he thought, he would lose his dog, and then advertise his dog, in connection with his name, in large capitals.

"Joining some church or other is another investment frequently made. Should you do this, pick out the most popular one with the fewest doctors in it. I have known some before now to change their church once or twice, hunting for the one, attachment to which would pay best. The old trick of being called out of church in the midst of the sermon is a very good one, which you might have repeated tolerably frequently—the old ladies will always notice it, and talk some about it after the service, and will be more apt to recollect you when they have a sickness at home. Always go into church late, when everybody is seated; you will thus be sure to be noticed by the congregation, and if you don't have a confederate to call you out during the preaching, you can leave just at its conclusion, as if compelled to hurry away on account of the urgency of your business. Standing in the doorway of the church, or just outside, and bowing to, and shaking hands with as many of the congregation who pass out as you can, is also very profitable in its way. It is a gentle intimation to the congregation that you are their representative in physic, and that it is their doctrinal duty to employ you. Your politics you may make equally subservient to your ends as your religion: these are the days men trade in both. . . . . When you have attended a case, and it has recovered by virtue of your treatment, or in spite of it, don't omit any opportunity of reminding your late patient and his friends of the fact, enjoining upon them the propriety of always remembering the bridge which has carried him over safely. When a man has employed you once, try to impress him with the idea that you have personal property in him, and that you shall be justly incensed if ever he shall change you for anybody else. On at any time learning that he has employed another doctor, go to him and ask him why he has ceased to employ you, and tell him that your feelings are hurt.

"Another art of great value is in certain cases where the opportunity presents to substitute a grave affection for a simple one in your diagnosis, express the most serious apprehensions as to the result, and allow the report to go out that Mr. A. or Mrs. B. is very dangerously ill. I have known some doctors never let an opportunity slip to magnify the danger of the disease and the value of their services; they gravely inform their patients that it was lucky they sent for them just when they did, for it was by their timely arrival and puissant intervention that a mighty fever was prevented, and if they had not gotten there just when they did, and done the peculiar things which they did do, the bellyache would soon have run into a *typhlo-enteritis with intussusception*, &c."

You will observe, Mr. Editor, that all these suggestions are also intended to accord with the letter of the code.

Hoping soon to see an announcement of the work on *Abrasions*, now in preparation by the "Successful Practitioner," I am, very respectfully,

A CONSTANT READER.

DANVILLE, KY., Jan. 25, 1880.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 1 to February 7, 1880

DE HANSE, J. V., Capt. and Asst. Surgeon. Granted leave of absence until further orders, on account of sickness. To take effect February 1, 1880. S. O. 26, A. G. O., February 3, 1880.

HANSE, C. B., Capt. and Asst. Surgeon. The leave of absence granted him December 20, 1879, from A. G. O., extended four months. S. O. 27, A. G. O., February 4, 1880.

CUNNINGHAM, Thos. A., 1st Lieut. and Asst. Surgeon. Granted leave of absence for one month, with permission to apply for one month's extension. S. O. 11, Dept. of Dakota, January 26, 1880.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending February 7, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Jan. 31, 1880...	0	3	54	3	234	52	0	0
Feb. 7, 1880....	0	6	51	0	240	34	0	0

A CURIOUS ACCIDENT. Dr. Z. E. Lewis, of Hunt's Point Road, Morrisania, New York City, writes: "You may be interested in an accident having lately happened to a patient of mine, which I think is unique. He had been raking over college experiences with some old classmates amid such hilarity that the tears had freely flowed, and found, on returning home, that one of his eyes was decidedly irritated. He could discover no foreign body, and, as the irritation was not extreme, he allowed thirty-six hours to elapse before consulting me. On everting the lower lid there appeared a hair like one of his lashes, or a fine hair of the beard, protruding from the lower punctum lacrymalis, about one-sixteenth of an inch, which, withdrawn, proved to have had more than two-thirds of its total length lying in the canaliculus. It was stiff enough to make considerable pressure upon the globe; its removal was followed by immediate and complete relief of all irritation."

OUTBREAK OF SMALL-POX IN A GERMAN PRISON. — In the penitentiary at Nangard, Prussia, fourteen prisoners were attacked with small-pox between the 12th of August and the 22d of September of last year. Most of those attacked had been employed in combing and spinning Russian hemp, while of a number of prisoners who were working on Manilla hemp in the same house not one was attacked. The Russian hemp used in the prison came from the department of Orel, which has been repeatedly devastated by small-pox of late years. As hemp is known to be a substance which retains the virus of small-pox for years in an active state, especially when kept secluded from the air, and no other source of contagion could be discovered, it was regarded as most probable that the disease had been conveyed to the prison in the hemp. In the Prussian regulations for 1885, hemp is classed with flax and tow as a poison carrier, but in the regulations for this year concerning the prevention of the introduction of contagious diseases into Germany, it is not included among the articles whose importation from Russia is forbidden. — *Lancet and Clinical Lect.*

FRENCH AND AMERICAN QUININE. — Dr. G. R. Black writes an interesting article in the *Cincinnati Lancet and Clinic* on the comparative value of French and American quinine. He noticed that the American quinine which he had been using, failed to produce the usual certain effects. He changed it for a French preparation, and got better results than ever before. Ten grains of this produced more powerful effects than fifteen of the old kind. Microscopic and chemical tests proved it to be purer also. As the general impression has been that foreign quinine is always inferior, the observations of Dr. Black are of considerable interest.

PORT PHYSICIAN AT BOSTON. — Dr. Swift, the Port Physician, having resigned, the Board of Health has promoted Dr. Woodbury, the Assistant Physician at the quarantine, to the vacant place.

LONDON LECTURE COURSES. — The Gulstonian lectures will be delivered this season by Dr. Gowers; subject, "Epilepsy." The Croonian lectures, by Dr. Cayley, on "Some Points in the Pathology and Treatment of Typhoid Fever." The Lumleian lectures by Dr. W. Roberts, on "Researches on the Digestive Ferments and the Preparation and Use of Artificially digested Food."

A CHEAP AUDIPHONE. — Dr. C. S. Turnbull, of Philadelphia, makes an audiphone similar to that of Rhodes, out of well callendered binders'-board. It costs but a few cents, and is quite as good as those of hard-rubber.

DEFENCE OF MAGENDIE. Dr. John C. Dalton has an article in the February number of the *International Review*, upon Magendie. He defends the character of that distinguished physiologist, and also makes a defence of vivisection.

LECTURESHIP AT RUSH MEDICAL COLLEGE. — At the *comamen* for the lectureship on Gynecology at Rush Medical College, held January 6th and 7th, there were six contestants. Dr. E. B. Ellis lectured on "Abscess of the Vulvo-vaginal Glands;" Dr. D. T. Nelson, on "Sympathetic Disturbances;" Dr. W. L. Ransom, on "Membranous Dysmenorrhœa;" Dr. D. C. Camp, on "Peritonitis;" Dr. A. J. Stone, on "Sarcoma Uteri;" Dr. R. S. Sutton, on "Dermoid Cysts." The choice lay between Drs. Nelson, Stone, and Sutton. The place was finally offered to Dr. Sutton, of Pittsburgh, provided he came to Chicago to live.

THE NEW ANÆSTHETICS. — Nitrous oxide and oxygen under pressure, the bichloride of ethidem, and hydrobromic ether, are the new anæsthetics which are now being tested. Hydrobromic ether is the last, and has been used with good results in a number of cases by Drs. Turnbull and Levis, in Philadelphia.

CHRONIC CONSTIPATION. — In a certain class of cases where the intestine is in an atonic condition, as in convalescence from fever, or in dyspepsia, Dr. Da Costa finds ext. belladonna fl. ℥ i. doses a most excellent remedy. In two cases related in the *Phila-*

delphia Medical and Surgical Reporter, the treatment was a tablespoonful of sweet-oil at night and a minim of the fluid extract of belladonna three times a day. The immediate good results were shown to be due to the belladonna.

Sea-water Baths.—The acknowledged value of sea-water bathing has inspired an enterprising company in London to supply that city with water from the English Channel. It is proposed to furnish it to every house for about $8 per year.—*Med. Press and Circ.*

Identity of Croup and Diphtheria.—An article by Dr. J. H. Stallard, in the *Western Lancet* for January, gives certain facts tending to show the identity of croup and diphtheria. The vital statistics in San Francisco during the last four years show that croup has increased and diminished in frequency in the same ratio as diphtheria. It also shows that the localities where diphtheria has most prevailed have been those where there has been the most croup.

Another Monstrosity.—A pair of female twins united from the breastbone to the lower part of the abdomen is reported from Bombay. They are nine months old and in good health.—*Med. Press and Circular.*

Celery as an Anti-Rheumatic.—Celery has always had some reputation as a nervous sedative. Its supposed efficacy in heart complaints has also long been a subject of facetious remark among the young at the dinner-table. It is now claimed that when cooked it is a preventive of rheumatism. When cooked it is a palatable dish, and, according to the *Louisville Medical News*, has a delicate flavor and a glutinous consistence like okra.

Dr. Richard C. Thomas, of Bowling Green, Ky., died on December 28th, in his forty-first year. Dr. Thomas was a skilful physician, and one of the leading members of the profession in Kentucky.

Defence of Opium-Smoking.—A consul at one of the ports of China thinks that opium-smoking is not so great an evil to the Chinese as is supposed. He says that the Chinese are remarkably free from bronchial or pulmonary complaints. Among the Christianized Chinese, however, who have given up opium, consumption is very frequent. There is no doubt that the Chinese are a very strong-lunged race. Whether the opium habit has anything to do with it or not, it is hard to say. The consul referred to has met numbers of apparently healthy-looking opium-smokers who began the habit to cure the "spitting of blood."—*Western Lancet.*

The Cure of Cataract by Electricity!—Under the head of science, a recent number of the *Churchman* has published a glowing editorial puff of a New York practitioner and electrician, well known to readers of this journal. It will no doubt delight members of the profession, and oculists in particular, to be informed, on the authority of the *Churchman* (which claims positive knowledge), that Dr. Neftel cures cataracts (what kind and what stage of development the *Churchman* omits to mention) by certain electrical manœuvres.

An Open Urachus.—Dr. John C. Pennington, Andover, Mass., writes: "I have at present under observation a case of retarded development which may be of sufficient interest to warrant its being made public. The patient is at present one year old. After birth the cord was tied as usual (by another physician) and separated on the third day, and shortly after one of the so-called 'granulation tumors' sprouted from the umbilicus, and has been there ever since. The physician in attendance wished to remove the growth by the knife, but was not permitted to do so. At present the little tumor is about the size and color of a medium sized raspberry, and presents a central aperture which will admit a silver probe to a distance of at least three inches. There is a certain amount of oozing, but, owing to the small quantity, and its being mixed with secretion from the surface of the growth, it has not as yet been possible to say with any certainty whether it be urine or not. If this be a case of *open urachus*, which seems probable, it is a very rare occurrence. Erichsen does not mention it, and Bryant has only seen one similar case. The child is healthy, and I should expect to see the canal close after a time, especially if the process is aided by stimulating its surface. I should be grateful for suggestions or experience on this subject.

Chloroform Deaths.—It is not easy to keep a record of all the cases of death from chloroform, so rapidly do they succeed each other. There is one reported now from St. John, New Brunswick. The patient was a boy of eighteen, suffering from an accident to the left foot. Only three drachms of chloroform were used. A post-mortem examination showed hepatization of the left lower lobe of the lung and congestion of the remainder of the lungs. The left side of the heart was empty; the right distended with blood. The coroner was of opinion that ether should have been employed.

A second death is reported as having occurred at the Chicago Eclectic College on the 3d ult. in the presence of the class. The patient was a robust young farmer, but exceedingly nervous. He was to have been operated on for necrosis of the tibia. Before he had been fully gotten under the influence of the anæsthetic respiration stopped and it could not be restored.

It seems likely that, with the record which chloroform is making for itself, its use will, except in particular conditions, be considered criminal.

Circular in Regard to Diphtheria.—The Boston Board of Health, following the example of other boards, has issued a circular for the purpose of more widely extending the well-attested facts about diphtheria, and of indicating the precautions to be taken for preventing the spread of the disease. These circulars are sent to all the secular papers, as well as distributed to individuals.

The White Mountain Medical Association held its annual meeting at Wells River, Vermont, on January 28th and 29th.

An Anti-Scorbutic.—During the long voyage of Professor Nordenskjold around the north coast of Asia, not a single case of scurvy occurred. This was due to the use of a small red berry that springs out of the ice and snow in the short summer. It is dried, mixed with reindeer's milk, and carried in a frozen state. It has a pleasant, slightly acid taste.—*Brit. Med. Jour.*

Modifications of the Politzer Method of Inflating the Middle Ear.—In inflating the middle ear, Dr. Holt employs a modification of Politzer's method, which does away with the swallowing of water. He directs the patient to fill the mouth tensely with air, while the air-bag is discharged as in the

ordinary way. Dr. J. O. Tansley, one of the clinical assistants at the Manhattan Eye and Ear Hospital, has modified Dr. Holt's method. He causes the patient to pucker up his lips and blow from the mouth while he forces air into the nasal cavity with the bag.

Counter Prescribing.—Mr. S. W. Gillespie, a pharmacist of Birmingham, Ala., offers the following suggestions regarding "counter prescribing:" "With reference to the article headed 'Doctor *v.* Apothecary,' which appeared in a recent issue of your journal, I desire to make a few suggestions, which I have never seen in any of the pharmaceutical or medical journals. An experience of over 25 years as apothecary and pharmacist warrants me in stating that nine persons out of ten who apply to the druggist for medicine do not ask for a physician, and it certainly is not a self-imposed duty for the druggist to force one on his customers and refuse them medicine because they won't seek the advice of the physician. He can recommend them to consult a physician first, but nothing more; this plan I have invariably adopted, but, unfortunately, with great pecuniary loss. The business of the apothecary is to supply the wants of his customers as promptly as possible, endeavoring to give the best satisfaction for value received without asking too many questions; and the poor druggist alone ought not to be saddled with the education of the public to seek a physician first before taking every dose of medicine he needs. It is in elevating the public mind to the necessities and demands of an independent medical fraternity that physicians must look for any redress to the seeming antagonism. The evil could be greatly mitigated if physicians would possess sufficient courage and manliness to recognize only the true apothecary from the numerous patent medicine humbugs and whiskeyites, thereby encouraging our pharmaceutical societies in their noble endeavors to wrest the profession of the pharmacist from out of its present accompaniments."

Regulating the Sale of Poisons.—The sale of poisons is intended to be sharply restricted by the provisions of a bill introduced into the Senate by Senator Astor, which proscribes the selling of arsenic, strychnine, and a variety of other poisons, except paregoric and preparations of opium containing not more than two grains of a poisonous substance, and except they are exposed in a particular kind of bottle labelled "Poison," and except also that it is sold on the prescription of a physician, and the entry on a book of the name, address, and occupation of the purchaser.

Dr. A. L. Bowditch has resigned his position as member of the Massachusetts State Board of Lunacy and Charities. He assigns as his reason the fact that the duties of the place are too arduous and exacting to allow him properly to carry on his private professional work. Dr. Bowditch was Chairman of the State Board of Health when it organized in 1869. He has been upon it ever since, and his retirement now is rightly considered a great loss. Dr. Fulsom is said to be a candidate for the vacancy.

The New York Microscopical Society held its Second Annual Reception on Feb. 6th, in the Sunday-school room connected with Dr. Bellows' church. A large number of microscopic objects were on exhibition. The retiring president, J. D. Hyatt, delivered an address recounting the microscopic progress, and the work of the Society during the past year.

An Appropriation has been made by the State Legislature to carry out the laws relating to the inspection and destruction of diseased animals.

Granting Powers to Medical Societies.—A bill was introduced into the State Senate, on February 6th, giving certain medical societies power to hold real and personal estate to the extent of $20,000, and the State Medical Society to the extent of $5,000.

A Petition against Lunacy Reform.—A petition, signed by a number of members of the medical profession, and protesting against any attempt at asylum investigation or reform, has recently been drawn up in this city.

The bill to initiate a better system of care for the insane is a wise, moderate, and unobjectionable one. We must assume, in deference to the intelligence and sincerity of the petitioners, that they were not aware of its character when they made their protest.

With a very large annual increase in the number of the insane, and the complexities of the question becoming continually greater, it is much to be regretted that any influential members of the profession have lent their names against a temperate and well-considered effort to improve the system of insane asylum management.

Neurotomy as a Substitute for Enucleation of the Eyeball.—Professor H. W. Williams remarks concerning this new operation, in the *Boston Medical and Surgical Journal*, that "neurotomy is probably of too recent application to warrant us in asserting positively that it will invariably be a preventive of sympathetic ophthalmia. Thus far, it has generally seemed effectual. Should any symptoms afterward manifest themselves, the operation might be repeated, to cut any nerve-filaments which possibly had escaped division at the time of the previous section. In case of failure as regards permanent relief, enucleation will still remain as an ultimate resort."

Dr. Le Moyne's Crematory at Washington, Pa., has been used again; this time on the body of a young lady of Allegheny City. She is the second woman who has been cremated by modern methods.

NOTE ON CYSTORRHAGIA FROM RETENTION OF URINE.*

By JOHN W. S. GOULEY, M.D.,

PROFESSOR OF DISEASES OF THE GENITO-URINARY SYSTEM IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK; SURGEON TO BELLEVUE HOSPITAL, ETC.

When hemorrhage occurs from the mucous membrane of the bladder, the word cystorrhagia should be used in preference to hæmaturia, since the latter has a wider significance; being applied alike to the passage of bloody urine from the kidney, from its pelvis, from the ureter, the bladder, or the urethra. Cystorrhagia may occur as a consequence of disease, of injury, or of the too precipitate evacuation of an over-distended bladder. It is of the last-named cause that I now wish particularly to speak.

Civiale regards over-distention of the bladder as "the most common of all the causes of hæmaturia." This excellent observer says † "that when hæmaturia depends upon over-distention of the bladder by the accumulation of urine or by a forced injection, the blood seems to ooze indistinctly from every part of the mucous surface," but he does not explain the mechanism of this general oozing. Nor does Mercier, or any other author with whose works I am familiar, appear to solve the problem. I believe that generally there is no hemorrhage as long as the bladder remains distended; but the moment the distention ceases,—either by rupture of this viscus or by the too precipitate withdrawal of the urine or water through a catheter—the oozing begins, and this is due to rupture of thousands of the capillaries of the mucous membrane, owing to a sudden change in their condition. For in such over-distention of the bladder, the mucous membrane as well as the muscular coat is greatly over-stretched, its capillaries are likewise stretched and weakened in consequence. When, therefore, the mechanical support given by the accumulated urine is suddenly removed, the extreme tension of the vesical parietes is succeeded by extreme flaccidity; the almost empty capillaries are instantly gorged with blood, and their delicate walls give way before the sudden impulse of the refluent blood, which soon begins to ooze from thousands of minute rents of the mucous membrane.

It is well known that free hemorrhage often succeeds the escape of pus from large, tense abscesses that have been hastily emptied; and this phenomenon has generally and correctly been attributed to the too sudden removal of the pressure exerted by the pus upon the small vessels which lie almost naked on the wall of the abscess. If this be true here, why not so in a diseased bladder? The analogy is perhaps greater in those cases where hemorrhage has occurred from the surface of smooth membranes, such as that of the tunica vaginalis, after the sudden evacuation of large hydroceles, or as that of cysts of inordinate capacity which have been incised or tapped. The general oozing of blood, which sometimes occurs from the surface of a diseased peritoneum after ovariotomy, furnishes another illustration.

Since writing the above, I had occasion to read Horace Stapfer's thesis on vesical hæmaturia caused by tuberculization,* in which he credits Civiale with being the first to call attention to retention of urine as a cause of hæmaturia, but he says that "Civiale does not explain the mechanism of hæmaturia caused by retention of urine," . . . . and asks, "could it not be attributed to the sudden disparition of the pressure which the urine exerted upon the parietes of the bladder, similarly to the phenomenon observed after puncture of certain cysts of the thyroid body?"

I wish to be clearly understood as not claiming that hemorrhage invariably, though I believe it frequently, follows the precipitate evacuation of the over-distended bladder, for I have, on several occasions, suddenly withdrawn as many as four pints, and have read of one, and even two gallons being removed by the catheter without subsequent hemorrhage. The hemorrhages in question occur usually in middle and advanced life, especially where the vesical mucous membrane is not absolutely healthy, and in those patients whose blood-vessels are already weakening. Cystorrhagia from over-distention is very uncommon in young adults and adolescents, and of extreme rarity in children.

The explanation of cystorrhagia just given is applied more particularly to bladders which are not much altered by disease; but I have no doubt that hemorrhage does occur from distention of certain diseased bladders the moment the distention takes place, and this is shown in the first urine that appears, whereas, in the class of cases before mentioned, the first urine drawn is clear and entirely free from blood. In several such cases which Civiale cites he only incidentally states that the first urine expelled was always clear, and that blood appeared the next time the bladder was emptied. It is evident, in those cases, that the blood began to ooze only after the removal of the pressure exerted upon the capillaries by the urine. Mercier † makes a statement which corroborates this view; he says, "often two-thirds or three-fourths of the urine contained in the bladder come out free from blood, and it is only toward the end that the fluid appears redder and redder;" and he further says that "this appearance has been wrongly ascribed to the precipitation of blood in the basfond." He himself attributes the hemorrhage to the action of the muscular coat of the bladder, which, he says, fairly squeezes the blood out of the congested mucous membrane like water squeezed out of a sponge. Unfortunately, for this theory and for patients, the very reverse of contraction too frequently follows the sudden evacuation of the bladder. If powerful contraction could always follow the precipitate evacuation of the over-distended bladder, there would be no hemorrhage, or, if any occurred, it would soon cease, in consequence of this contraction of the muscular coat, and of retraction of the mucous membraue, and of its underlying connective tissue.

In chronic cystitis with sclerosis of the mucous membrane, retention of urine, giving rise to comparatively little distention of the bladder, will cause hemorrhage from cracking or tearing of the unyielding mucous membrane, and the first urine drawn will be bloody. Hemorrhage doubtless follows distention from accumulation of urine in other diseased conditions of the bladder, such as papillomatous, tubercular, or cancerous degeneration, etc.

A word here concerning diagnosis may not be out of place. The main point is to determine whether or

* Read before the Med. Soc. of the State of New York, Feb., 1880.
† Maladies des organes génito-urinaires, vol. iii., p. 360.

* Paris, 1874, pp. 8, 9.
† Recherches anatomiques, pathologiques, etc. Paris, 1844, p. 141.

not the hemorrhage be cystic, for the bladder may become filled with blood which has come from another source. For instance, there may be free bleeding from the kidney (nephrorrhagia), due to a laceration of the organ, to a vascular cancer which has finally involved its pelvis, to tubercular disease; or, the hemorrhage may be owing to extreme congestion, as that occurring after the ingestion of certain poisons—among others phenic acid, or, from prolonged exposure to the fumes of turpentine on turpentine ships or in shops. Within a couple of years I have had two cases of such hæmaturia, whose diagnosis was cleared by a few questions. Both men were workers in a varnish factory, and, for several weeks, had been passing bloody urine. They were advised to stop work, and, in a short time after, the urine became clear. My attention was called to this action of the fumes of turpentine many years ago, by the late Dr. Charles E. Isaacs.

There may be from the pelvis of the kidney very abundant and continuous hemorrhage. When this pyelorrhagia is the result of cancerous degeneration, it will not be long before the diagnosis is verified by an autopsy; but when it arises from other causes, such as parasites, it may remain obscure for a long time, if not altogether, unless careful and frequent microscopic examinations of the fluid be made. In other cases the diagnosis may be easy. One of my patients almost always, after drinking one or two glasses of champagne, suffers from hæmaturia (probably nephrorrhagia and pyelorrhagia) for two or three days, and, in the very bloody urine that he passes, is able to collect fifty or sixty round uric acid calculi, the largest of which scarcely exceeds in size an ordinary pin's head. The hemorrhage may be from the ureter (ureterorrhagia), and may be caused by a rough calculus during its transit from the renal pelvis to the bladder. The urine passed by such a patient sometimes contains long, leech-like clots, and this fact, taken in conjunction with the general symptoms, leaves no doubt as to the origin of the hemorrhage. In a case of very persistent hæmaturia, I was able to determine the source of the hemorrhage from the several circumstances presently to be stated. The first was, that no retention of urine had occurred; the second, that the urine ordinarily contained at least two-thirds blood; the third, that it was at times perfectly clear; the fourth, that the hemorrhage would be preceded by a very distressing ureteric and pyelic colic on the right side; and the fifth, that the urine frequently contained firm bdelloid clots five or six inches long. These facts, together with the existence of a tumor in the right flank, led me to regard the case as one of ureterorrhagia, due either to an impacted calculus, or to malignant disease. The patient died in the course of a few months, and the autopsy revealed a very vascular, primary cancer of the right ureter, a little above its middle.

I have said that the bladder may be rapidly filled by blood coming from some one of the sources before named, but if the blood does not as rapidly coagulate, it will be expelled; and if by good luck its flow into the bladder be checked, as was shown in the case of cancer just mentioned, by impaction of a clot in the ureter, there will follow ureteric and pyelic colic, and while this lasts, the urine secreted on the sound side—at first tinged by the little blood remaining in the bladder—will come away clear, and as soon as the impacted clot is dislodged and carried into the bladder, the urine will again be bloody. It may be proper to syringe out the bladder during the ureteric colic, in order to wash away the remaining blood, —then if the water afterward injected comes away clear, it is reasonable to suppose that the hemorrhage is not cystic.

But if the hemorrhage has been so abundant as to cause great distention of the bladder, with clots, the case will be attended with a twofold danger, and the prognosis may be unfavorable; for if then the distended bladder be suddenly evacuated, there will probably be hemorrhage from its mucous membrane in addition to the bleeding which may have come from the ureter, renal pelvis, or kidney. When all the sources of hemorrhage already indicated have been excluded, and the loss of blood is not from the urethra (urethral hemorrhage can be at once diagnosticated by passing a catheter into the bladder. If, after the first ounce or thereabouts, the urine drawn be limpid, it is certain that the blood which had previously escaped had not come from the bladder. In some cases of hemorrhage from the deep urethra, the blood often enters the bladder, but this is easily made out)—then its vesical origin is fairly established.

Cystorrhagia is known to occur from ulceration of the bladder, from injuries inflicted by the movements of a calculus, from some forms of acute and chronic cystitis, from the perforation of small veins by certain parasites, from tubercular or cancerous disease, from papillomata, and from violence; but in the class of cases under consideration, retention of urine is its principal factor in certain instances of diseased, while in comparatively healthy bladders, or in the atonied bladders of elderly men with prostatic enlargement, its most frequent exciting cause is the sudden withdrawal of the urine by which the organ had been greatly over-distended.

The first urine drawn, as before said, is usually clear and free from blood, the second is blood-red; afterward it grows dark and dingy, until it becomes chocolate-colored, and finally assumes a tarry appearance and consistency, and acquires a disagreeable odor similar to that of decayed, dried codfish. These changes in the character of the blood are due partly to the action of the urine, partly to the admixture of mucus, of which there is hypersecretion, and to the development of ammonia. In such cases the effusion of blood is considerable, but not always sufficient for the formation of coagula; for as long as there is a fair proportion of urine, no coagulation takes places, but when the flow is rapid and exceeds the urine in amount, the bladder will soon be filled with clots, even to great over-distention. Cystorrhagia may last from a few hours to two or even three weeks if not checked by appropriate treatment.

The constitutional effects will, of course, depend upon the previous physical condition of the patient, the amount of blood lost daily, and the extent and severity of the ensuing cystitis. Prompt and intelligent interference will soon arrest the bleeding and generally save the patient. The danger to life is not so much from the severity of the hemorrhage as from the extent of injury to the capillary vessels and mucous membrane. What is here most to be dreaded is the supervention of general cystitis, which is so apt to be followed by double ureteritis and pyelonephritis. When these complications have occurred there is oliguria, then anuria which is soon followed by a typhoidal condition, with low muttering delirium, and death, all within a week or ten days after the first evacuating catheterism that had given issue to three or four pints of clear urine.

Perhaps the recital of the history of a typical case of cystorrhagia from the too precipitate evacuation of a distended bladder, taken from my note-book, will illustrate several important points that I may have failed to make plain.

On September 2, 1875, I saw, in consultation with a medical gentleman, in a neighboring city, Mr. S. B., aged sixty-three, who had "for ten years suffered more or less from his bladder," and had had occasional attacks of retention of urine, all owing to prostatic enlargement. Two years before our interview he had a retention of urine, relieved by the catheter which caused considerable urethral, but no vesical hemorrhage. On the evening of August 23, 1875, while sitting upon the stone steps in front of his house, he felt chilly, but thought little of this and went to bed at his usual hour. On rising in the morning he experienced trouble in voiding his urine, and was finally unable to pass a single drop. His bladder having become painfully distended in the course of twenty-four hours, he summoned his physician who relieved him at once, by the catheter, of about three pints of clear urine. A second catheterism, on the same day, gave issue to bloody urine, and from that time all the urine drawn off was highly charged with blood. On account of the persistence of the hemorrhage, the doctor requested me to see his patient. When I arrived at the house (at 3 P.M.) I found Mr. B., a pallid, slender-built man, walking the floor nervously, and in great agony from distention of the bladder, though the doctor had drawn off his urine in the morning. His general condition was fair, and he had had no febrile reaction for a week. On digital examination per rectum, the prostate was found tumid but not very large. A metallic catheter of short curve, similar to Mercier's, encountered a median prostatic obstruction, which was easily surmounted. A soft rubber Nélaton catheter, which was then introduced, gave issue to a pint and a half of fetid, thick, alkaline, tarry fluid, consisting of about an equal amount of blood and urine, but the blood was thoroughly mixed with the urine and there was no coagulum. I expressed the opinion that the blood had probably oozed out of numerous minute vessels from a considerable extent of the vesical mucous membrane. The doctor said that, at first, the hemorrhage was much more profuse, and that there were clots which frequently closed the eye of the catheter. Inasmuch as the bleeding had thus far been kept up by the frequent distention of the viscus, I suggested, as the prime indication in the case, complete drainage of the bladder for, at least, twenty-four hours. This was effected by introducing, and retaining in position, a gum-elastic Nélaton catheter. An occasional vesical injection of two ounces of weak tannin solution was also advised, likewise ice in the rectum, absolute rest in the recumbent posture, and twenty-grain doses of quinine dissolved in dilute sulphuric acid. The doctor had already given twenty-minim doses of fluid extract of ergot, and I advised their continuance. He had also irrigated the bladder with salicylic acid solution, with the effect of deodorizing the urine temporarily. From the time I introduced the catheter no more urine was allowed to accumulate in the bladder, and the blood was frequently washed away with the styptic solutions. This course of treatment had the effect, within two days, of arresting the hemorrhage and of controlling the consequent cystitis. I saw the patient in the course of two months, when he said that he felt as well as usual. Three years after, he had had no recurrence of hemorrhage.

PREVENTIVE TREATMENT.

If sufferers from prostatic and vesical trouble were always under the watchful eyes of intelligent physicians, their bladders would not be permitted to become over-distended, and this one cause of cystorrhagia would not exist. But as over-distention now occurs so frequently, let us see in what way relief may be given and cystorrhagia prevented.

Nothing can be more simple; the bladder should be emptied very gradually in the course of twelve, twenty-four, or forty-eight hours, and in certain extreme cases, even several days (as suggested by Sir Benjamin Brodie).* One of the ways of accomplishing this is to introduce a soft catheter and secure it in position, then to allow the urine to trickle through it slowly by partially obstructing † the distal orifice with a finger, so that in the course of five or six minutes not more than eight ounces will have escaped; and to repeat this every two hours until the bladder is emptied. If the urine drawn be very fetid, the process should be modified as follows: immediately after drawing the first half-pint of urine, eight ounces of warm water, in which has been dissolved a scruple of biborate of soda, should be injected into the bladder, then a pint of urine drawn, and at once half a pint of borax solution thrown in. This should be repeated at the first sitting six or eight times, or until the whole of the offensive urine is gotten rid of, and the bladder contains nothing but the clear borax solution; then every two hours, and in some cases even every three hours, half a pint of the fluid—now mixed with newly secreted urine—should be drawn off, until the bladder is completely empty. In this way a bland fluid will have been substituted for decomposed and irritating urine, the hydrostatic pressure will not have been removed too suddenly, and thus cystorrhagia will have been prevented.

Sometimes polyuria follows the first catheterism to such a degree as to make it necessary to draw off one instead of half a pint, and do this every hour instead of two hours, otherwise the vesical distention would be unrelieved. To illustrate this point, let me relate the history of a case of inordinate polyuria without glycosuria. I have never known a patient to secrete so much normal urine in the same space of time.

Mr. P. D., æt. 67, stout, weighing about 200 lbs., suffering from prostatic hypertrophy and stone in the bladder, was sent to me by a medical friend early in March, 1879. Mr. D. had, at different times, for a period of twenty years, passed gravel and also well-formed small uric acid calculi. He was subject to polyuria which would be caused by almost any diuretic. He could never take cider, ale, tincture of the chloride of iron, copaiba, or cubebs, without provoking great increase in the urinary secretion. For six consecutive weeks he passed four pints of urine daily, and for two additional weeks, six pints daily. At the end of that time—that is, March 1, 1878—his bladder became over-distended, and the urine came away guttatim. On this account he was catheterized, and three pints of clear urine drawn in the first hour at intervals of twenty minutes. The catheter was tied in position, and one pint of urine was drawn off every hour for twenty-seven consecutive hours, when the amount began to diminish until it was reduced to six pints every twenty-four hours. In the

* Brodie: Lect. on Dis. of Urinary Organs. London, 1835, p. 161.
† Civiale.

course of about three months it was gradually reduced to four pints, and so continued until March, 1879, when I relieved his bladder of the irritation which had been caused by several small stones. When he left the city, toward the end of March, he was making three pints of urine daily, and was in excellent physical condition.

TREATMENT OF CYSTORRHAGIA.

When cystorrhagia has taken place, besides enjoining absolute rest in the horizontal posture, the surgeon should take means to prevent the bladder from becoming distended with bloody urine. But if, when he arrives, he finds hypogastric dulness extending to or into the umbilical region, he should draw off, through a gum catheter, only a pint of urine, then throw in half a pint of the borax solution as mentioned under the head of preventive treatment—and draw half a pint of fluid, and repeat the process until the fluid becomes clear, or nearly so. Afterward, every hour or two hours, the stopper of the catheter should be removed, and half a pint of fluid allowed to flow, until the bladder is completely empty. For that purpose, the catheter should be retained in position twenty-four hours, very rarely longer. This drainage alone will often have the effect of checking the hemorrhage, especially if the muscular coat of the bladder soon begins to regain its contractility, which can be sometimes hastened by occasionally throwing in two or three ounces of weak, cold watery solution of tannin, of alum, or of almost any other astringent. Ice in the rectum, applied according to the plan of Cazenave, is a valuable adjuvant.

The next indication is to guard against general acute cystitis, the supervention of which would be the most serious accident that could well happen in such cases, except, of course, rupture of the bladder.

Hemorrhage is more apt to recur in cases of pre-existing atony of the bladder. Therefore, it is important to begin to treat this atony as soon as the bladder has been emptied.

When cystorrhagia occurs in cases of cystitis, with sclerosis of the mucous membrane, whether the distention be caused by retention of urine or by a forced injection—which latter is sometimes used in their treatment—drainage is essential; no urine should be allowed to accumulate, and styptic injections in small quantities should be employed, and gallic acid, or some of the other hemostatics, will be indicated. In such cases the hemorrhage is not usually abundant. The danger lies in the aggravation of the cystitis.

The most serious hemorrhages are those which occur from papillomatous or cancerous tumors. I have a specimen of the former, in which hemorrhage was the immediate cause of death.

Although so great an authority as Civiale seems to attach little importance to general treatment, I am sure you will agree with me that it has its utility, and should not be rejected. I would recommend the exhibition of ergot (15 to 20 minims of the fluid extract every two or three hours), or of gallic acid, dissolved in glycerine, or of quinine, with an equal quantity of dilute sulphuric acid, or of tincture of the chloride of iron, etc. All these medicinal agents have their value, and any one of them will often answer the purpose. But when the desired effect has been obtained, the dose should be reduced, and the medicine discontinued as soon as possible, otherwise the digestive organs will surely suffer.

When it happens, in cystorrhagia, that no fluid runs through the catheter after it has been successfully introduced into the bladder, it may be that a clot has become impacted in the catheter, or that the bladder is filled with coagula, and little if any urine.

What, in like circumstances, should be the conduct of the surgeon? He should withdraw the catheter, and if he find in it a clot, wash it out, or take a clean catheter and introduce that, and if there be fluid blood and urine, it will of course flow freely. But suppose the bladder to be filled with clotted blood, what then is he to do? In this there is a difference of opinion.

Chopart advises the injection of water through the catheter to break up the clots, and if they do not come away, to introduce into the distal end of the catheter the nozzle of a syringe with which to make aspiration of the broken-down clots, and cites several cases in which this was successfully accomplished. A number of his contemporaries had like successes. Howship, and also Sir Benjamin Brodie, advocated this process.

Phillips cites Leroy as having extracted a little more than four pounds of coagula from a man's bladder, with the aid of aspiration made through a catheter which he was obliged to introduce one hundred and fifty times in the space of six hours.

Though Civiale approved of repeated injections of warm water to soften or dissolve the clots, as recommended by Verdier, he condemned aspiration. Other modern surgeons are against aspiration of the clots, but their objections are not tenable. The principal objection made is, that the removal of the clots will excite fresh bleeding either by affording a cavity into which more blood may be poured, or by allowing the plugs to escape from the torn extremities of the capillaries. They also urge that the clots do no harm, and will, in a couple of days, be dissolved by the urine. It is a misapprehension of the true state of things that has led the opponents of aspiration to condemn this practice, inaugurated as it was by some of the best surgeons of the last century. Injections and aspirations properly done, cannot and will not give rise to fresh bleeding; it is the hasty removal of the contents of the bladder, as I think I have shown, that will provoke hemorrhage, and it is the very thing which every good surgeon should avoid. It is not good surgery to allow a bladder to become over-distended with blood and then to wait forty-eight hours for the urine to dissolve the clots, while the patient is in the throes of vesical distention and tenesmus. I think that in such a case the indications *for* mechanical interference are exceedingly plain. But, I repeat, the vesical contents must *never* be hastily removed, otherwise there will necessarily follow fresh hemorrhage. In endeavoring to free a bladder greatly distended with clotted blood which cannot pass through an ordinary catheter, the way to proceed is to use a soft catheter with one large eye, or a metallic Mercier catheter as large as can be introduced, then to inject two or three ounces of warm borax solution (diluted acetic acid has been recommended for dissolving clots); if nothing flows, the instrument should be moved gently to and fro and rotated to the right and left so as to break up the clots; then aspiration made either with a syringe, as recommended by Chopart, or with Bigelow's rubber-bag. No attempt should be made to aspirate more than three or four ounces of clots, or grumous blood, at a time. The surgeon should continue, at the same sitting, to make alternate injections and aspirations, never with-

drawing more than he has injected, so that the contents of the bladder will remain about the same, until all the blood has been removed and the returning liquid is nearly clear. After this, every hour or two hours, as the case requires, a few ounces, rarely more than eight, should be drawn off until the bladder is empty. Gallic acid or other agents can, in the meantime, be administered, and afterward the bladder may be irrigated with such astringent solutions as are necessary. I feel quite sure that such a course would not only prove efficient, but much safer than the expectant plan just referred to.

"When the coagula are not dissolved," says Paul of Aegina, "make an incision in the perinæum as in cases of calculus; and having removed the clots of blood, accomplish the cure in a proper manner." This operation of perineal cystotomy was revived by Larrey and others of his time, in cases where the clots were too dense to be broken up by the catheter. The operation is reported to have been performed under the auspices of Sir Astley Cooper, by Mr. Copeland Hutchinson, with the result of extracting a pound of coagula, but the patient died in three days. Civiale very properly condemns this heroic and ordinarily unjustifiable procedure, and suggests in its stead the employment of the lithotrite to break up the clot when it is too dense to be reduced by the catheter or aspirator.

THE PROVIDENT-DISPENSARY SYSTEM AND THE ABUSES OF MEDICAL CHARITY.

By C. L. DANA, A.M., M.D.,

NEW YORK.

It is known that a very large number of the persons who receive gratuitous medical relief at dispensaries are not deserving of such charity. It is estimated that nearly one-half could pay a respectable fee if they chose, and a still larger proportion could pay if they were provident.

This whole matter has been much more carefully studied in England than in this country. The facts collected as to the abuses there are somewhat startling, yet they represent to some extent our own condition, and are therefore worth repeating.

At Queen's Hospital, Birmingham, it was found, in 1878, that ten per cent. of the out-patients could afford to pay a doctor's bill, in lump, of four or five pounds. Two-thirds of these same patients were able to pay for medical relief under the provident plan. At the Royal Free Hospital, London, only twenty-six per cent. of the out-patients were fit objects of medical charity. Other out-patient departments, when investigated, revealed a similar state of affairs. In London it is estimated* that one in four of the whole population receives gratuitous medical advice when ill; in Birmingham the proportion is 1 to 3.6; in Liverpool, 1 to 2.

Further than this, there is every reason to believe that the practice of resorting to free dispensaries is rapidly increasing. In Birmingham the increase in the number of out-patients from 1867 to 1876 was 50 per cent.; the increase of population was only 13.8 per cent. This is no exception to the experience of other towns, and it is safe to say that it fairly represents the state of things in many of the large cities in the United States.

* H. C. Burdett: "Pay-Hospitals of the World."

It will be readily acknowledged that the results of such indiscriminate medical alms-giving are demoralizing to the recipients as well as disastrous to our profession. I do not propose to enlarge upon these points, but to give some account of a system that has been proposed, and, to some extent, tried as a remedy for the increasing evil.

For many years there have been in England what are known as Benefit, or Friendly Societies. These are guilds composed chiefly of workingmen. They pay annual dues, and out of the fund thus created a doctor is hired, who treats the members when they are sick. These institutions are limited in membership, however, and embrace but a small part of those needing medical relief, yet unwilling to be classed as paupers. Something with a wider scope was needed, and therefore the provident-dispensary system was introduced.

Provident dispensaries have existed in a few of the smaller cities of England for over forty years. Institutions of a similar kind have also existed for a long time in Germany. There the workmen in certain towns support their own hospital and dispensary. These provident dispensaries are simply mutual health associations. They embrace only those who do not earn over a certain small sum—say $10 per week. Annual or monthly dues are required. When a member is sick, he receives medical attendance free. He may even have a nurse provided for him, and, in case a hospital is necessary, arrangements are made which allow him to be taken there.

Provident dispensaries on the above plan first began to be prominently advocated in England about twelve years ago.

At a meeting of medical men, held in London in 1867, over which Sir William Ferguson presided, it was voted the opinion of the meeting "that the evils above referred to could be, in a great measure, met by the establishment on a large scale of provident dispensaries, not only in the metropolis, but throughout the kingdom, and by improved administration of poor-law relief." In 1871 the matter was again agitated, but it was found that the influence of the free dispensaries and out-patient departments of hospitals was a very great difficulty in the way of accomplishing anything. In the next four years, however, fifteen provident dispensaries were established and kept in good working order. An investigation during this time showed that about half the out-patients at hospitals had an income of from $5 to $7 per week.

In 1877 further action was attempted by a meeting in London, presided over by Dr. Acland, of Oxford. Many prominent laymen were present, as well as such medical men as Sir Wm. Gull, Sir Wm. Jenner, and Mr. Erichsen. The principal resolution was carried unanimously, namely: "That . . . while, on the one hand, out-patient departments should be regulated so as to secure the prompt treatment of cases requiring the special resources of a hospital; on the other, free dispensaries should be converted into provident dispensaries, and new provident dispensaries should be established in proportion to the wants of the population." A committee appointed at this meeting, of which Mr. Timothy Holmes was chairman, drew up a new and revised set of model rules for provident dispensaries. They also circulated a large number of tracts upon the subject.

In the summer of 1878, the authorities of St. Bartholomew's Hospital investigated the abuses of out-patient charity. They condemned the present system as "inadequate and unsatisfactory." They agreed that the establishment of a localized self-supporting

system of provident dispensaries, in subsidiary relation to the hospitals, would be an indispensable part of any scheme that might be proposed.

A third large meeting was held in the same summer to further this movement. Efforts were then initiated to secure the co-operation of the various benevolent societies of the city in forwarding the provident dispensary plan. It was proposed to organize a Metropolitan Provident Dispensary Union, with branches throughout the city. At a subsequent meeting in June, 1879, it was announced that this system of provident dispensaries was endorsed by most of the benefit societies and unions, as well as by the council of the Hospital Saturday Fund. A committee was appointed to draw up a plan for a Metropolitan Provident Dispensary Association, with branches throughout the city. This committee met in July, and organized a sub-committee to draft the specific plans.

Meanwhile, the British Medical Association, last summer, appointed a committee to examine and report on the Provident Dispensary System. Of this committee, Mr. T. Holmes is chairman. The editor of the *British Medical Journal*, Mr. Hart, has been active in forwarding the movement.

During the last few years, numerous provident dispensaries have been springing up in various parts of London, as well as in the provincial towns. A synopsis of the annual report of one of these will give an idea of the workings of the system.

The Salisbury Provident Dispensary, in its second year, announces that it received in dues $4,815. It has a membership of 6,200. In 1878 it divided $3,175 among its ten medical men. A comparison of reports shows that the memberships vary from 2,000 to 6,000. The members pay from 1d. to 4d. a week; 2d. a week is considered the proper sum. The cases of sickness per annum are generally about equal in number to the whole membership. The expenses vary, but it seems that when the receipts amount to the equivalent of about a dollar a year for each member, the expenses, including a moderate sum to the doctor, are covered. The membership is confined, as a rule, to those receiving weekly wages, *i. e.*, about £2 per week, and from that down. The medical officers receive one-half the entire receipts, and, in addition, £1 for each midwifery case, and two-thirds of any surplus that may remain after the expenses are paid. Medical men, honorary and provident members, form a committee of management.

Provident dispensaries, organized under such a plan as this, have received wide endorsement from philanthropists, medical men, and charitable organizations, and under the encouragement thus given, they are increasing in numbers every year. The great enemy to success in all cases has been the out-patient department of the hospitals. It has appeared most desirable that these institutions should co-operate with the provident organizations, making the latter auxiliaries and supplements to the former. This has actually been done at the Royal Albert Hospital, Devonport, and at the hospitals in two provincial towns; at these places, provident dispensaries flourish near to and under the countenance of, the hospitals.

In this country, so far as can be learned, New York city is the only place where, until lately, the subject of the abuses of medical charity has been agitated with the end of securing a practical remedy.

In 1877, the Public Health Association of New York appointed a committee to consider the practicability of introducing provident dispensaries. The matter was elaborately discussed, but no result came from the agitation. In 1877-8 the St. John's Guild appropriated $100, to see what could be done in the way of establishing the system. The English methods were but partially adopted, however, and a history of the movement would explain its failure.

As regards other methods of securing reform, in 1876 the New York Dispensary began to charge its male venereal patients ten cents for each prescription. In 1878, at the recommendation of Dr. Sturgis, this plan of charging was extended to all cases. A like system has been introduced into several other of our city dispensaries. The results have been to furnish sufficient money to pay for the medicines prescribed, and undoubtedly to keep away some persons who do not require medicine, or who, finding they have to pay a little, prefer to go to the doctor's office and pay the regular fee.

The pay system at free dispensaries, however, goes but a very little way in securing reform. In English practice, it has been found neither to cure abuse or lessen the number of applicants.* On the other hand, it introduces fresh evils, among which are the practice of begging money from house to house, and of lying, in order to get rid of paying the required fee. In addition to this, free dispensaries are established for those who cannot pay, and it is a violation, to a certain extent, of their original purpose to enforce the fee system. There is also a danger that the patient who pays ten cents, may go away with the feeling that he has returned an equivalent for the service rendered. It is not desirable to cultivate the impression that a medical service is of so little value.

There are now in this city a considerable number of benefit societies or unions, which hire a doctor to treat their members.

There have been efforts also to establish so-called "provident dispensaries" on a small-fee basis. The patient who applies, pays twenty-five cents, and gets treated once; or he pays one full fee, and gets treated for the whole subsequent thirty days. This plan is manifestly liable to great abuses.

The evils of indiscriminate medical charity have recently been discussed in Philadelphia, and a committee has been appointed, representing the various city hospitals and dispensaries, to investigate the dispensary system, and secure greater care in the method of doing work.

Although the subject has been brought up and discussed in other cities, I am not aware that any positive action has been taken to secure reform.

From the trials thus far made, and from the opinions of those whose experience is widest in the matter, it seems necessary to conclude that the provident dispensary system is the one which goes farthest in affording a solution to the difficult question of the abuses of medical charity. There is a large number, though not a majority, of dispensary patients who cannot afford even to join such a dispensary. There is another large class who can afford to do so, but who will not. They are the improvident, who prefer to spend their extra quarter in rum, and then get treated gratuitously for the cirrhosis. There is a third class who cannot afford to pay a doctor's fee often, if at all, and yet who would be willing to pay something toward it. It is among those, the sober workmen and workwomen, the small tradesmen, perhaps clerks with small salaries and large families, shop-girls, and domestics, that provident dispensaries

* Vide op. cit.

would do a vast deal of good. Their example of providence might also influence their improvident neighbors. Eventually, if example failed, municipal and dispensary regulations might compel many of the second class to habits of providence. The co-operation of free dispensaries, as has been stated, is quite essential to a full and extensive introduction of the provident system.

And this suggests that there are many difficulties in the way of establishing these dispensaries. Money will be needed to set them going and help them until they are self-supporting. A large number will be required; for it is safe to assume that there are over 150,000 people in the city who could properly join them. Then there will be strong opposition, though it may be only indirect, from many of the established free dispensaries. This is especially the case with the dispensaries that furnish clinical material to the colleges. These always have been, and, it is to be feared, always will be the enemies of a provident system. Of the forty dispensaries in the city, however, less than half a dozen furnish clinical material to any large extent. In this respect we have an advantage over London.

There are also certain dangers to be remembered in recommending this dispensary system. Irresponsible parties will be sure to assume the name and the virtue, although they have neither. Every institution, therefore, should be started under public and responsible, not under private management. It might be well for county medical societies to keep a list of the legitimate institutions and issue certificates of regularity to them.

But, whatever the dangers, it must be remembered that the advantages of the system have already been observed. So-called provident dispensaries will soon spring up in any event. It will be better, therefore, for reputable men to take hold of the matter and preoccupy the field. We may sum up, then, the whole matter:

Most serious evils exist in the present mode of bestowing medical charities. It is probably a low estimate to say that $150,000 are expended yearly by the lower classes in alcohol and other things, not necessaries of life, which should go legitimately toward the payment of medical services.

The provident dispensary system is the most efficient one which reason and experience have yet suggested as a remedy.

Its benefits would be: to give better medical and sanitary care to the poorer classes; to teach them self-respect and habits of providence; to furnish a juster remuneration to physicians for their labor.

It has been shown that it is a practical system and can be made self-supporting.

Its difficulties in this city are not insurmountable, and its dangers will not be lessened by leaving the matter alone.

I have by no means exhausted the subject. I have, indeed, touched but briefly upon the details of its practical workings. These have been well matured and are embodied in a pamphlet, referred to already, and entitled "Model Rules for Provident Dispensaries," published by the London Society for Organizing Charitable Relief. I have simply tried to present the facts in the matter, in the hope that a knowledge of them may lead to a fuller discussion, and, if deemed advisable, to some definite action.

62 West Forty-sixth Street.

Gratuitous Medical Relief is to be given to about one-fourth of the sick in Chicago.

EFFECTS OF COLOR ON DISTANCE.

By C. A. BUCKLIN, M.D.,

new york.

That artists unconsciously avail themselves of a universal visual imperfection in producing distance on canvas, is a fact which in interest is only exceeded by the fact that all eyes have visual imperfections.

Let us compare, experimentally, the human eye with a simple optical instrument, and we will find that the eye has even more defects than the instrument.

I. If we allow a ray of sunlight to fall upon a prism of glass, after passing through it, the ray divides itself into various colors; they are all bent toward the base of the prism; the violet rays are bent the most, the red rays are bent the least.

This demonstrates that the red rays are more difficult to bend than the violet.

II. If the light from a candle, twenty feet distant, falls upon a common magnifying-glass (No. 2), the rays will be united in one point about two inches behind the lens. If we place a sheet of paper at this point we will see formed upon it a round point of light; if we carry the sheet of paper a few inches farther back, a distinct inverted image of the candle will be seen. If the candle is then brought a little nearer to the lens the image will vanish, and the former round light point will gradually take its place, which indicates that the rays are united farther behind the lens than they were. That is, by bringing the candle nearer we have made the rays more difficult to bend or unite.

Bringing the candle nearer make the rays diverge, and diverging rays of light, as well as diverging projectiles, are difficult to make converging.

We have seen that red rays were more difficult to bend than violet.

Now we have found that divergent, or rays from a near object, are difficult to converge.

This makes it evident that *color* and *distance*, independent of light and shade, are interchangeable. A lens should unite rays from violet objects and rays from red objects at the same point; but a simple lens does not.

The discussion between Newton and Euler as to whether this error existed in the human eye, is not without interest. Newton's belief that the eye was not achromatic, and also that it was impossible to produce achromatic refractive instruments, led to his inventing and constructing the reflecting telescope.

Euler's incorrect belief that the eye was achromatic, led to the construction of achromatic telescopes and microscopes.

We have but to compare the glass lens with the lens in the human eye (as was done by Maurolycus in the last half of the sixteenth century). The sheet of paper representing the retina, the candle the observed object, and the dark space intervening between lens and paper, the dark chamber of the eye. Thus we have compared the eye with a simple optical instrument. The chromatic aberration of the human eye is considerably less than that of a glass lens.

Without referring to the details of Fraunhofer's* experiments, by which he not only demonstrated the existence of this error in the human eye, but with which he measured it, I will give you his results. At the far point of distinct vision, with the eye at

* Mauthner: Optische Fehler des Auges, p. 35.

rest, a violet object must be twenty-six inches nearer in order to be seen with the same distinctness as the red object. Artists all agree that independent of light and shade, coloring parts of a painting violet retires them, while coloring them red advances the same. I consider that their success in producing this effect depends principally upon this universal visual imperfection in the human eye.

If I have succeeded in calling the attention of those who have but little time to study optics to the fact that all eyes suffer from chromatic aberration, and have given them a general idea of the nature of this visual imperfection, my aim has been reached.

ON THE TREATMENT OF TUBERCULAR CONSUMPTION.

By CARL BOTH, M.D.,

NEW YORK.

Some time ago I published an account of a treatment of tuberculous phthisis, which I had used with good success for twenty-two years. That treatment consisted in, *first:* The cleansing of the bronchi of mucus and pus, and afterward the normal expansion of the air-vesicles by means of actively exercising the respiratory muscles (See MEDICAL RECORD, of July 21, 1877, and May 18, 1878). *Second:* The careful study of the needs of the system for certain articles of food containing lime salts; and a proper appreciation of the necessity of getting rid of excrementitious substances as quickly as possible. *Third:* In a medication of certain minerals in organic form, such as lime and silica, for the purpose of aiding the calcification of tubercles; and in acids, such as citric, which contain an excess of oxygen, and which tend to help the oxidation of protein substances. *Fourth:* In bringing the patient in such condition of life that his nervous system is not unnecessarily overtaxed, at the same time it is so employed as to balance nervous force and stimulate his general nutrition as much as possible.

The whole object of this method, which I have called that of the "artificial calcification of tubercles," is to check the suppurative processes and arrest the softening of the indurated portions of lung. It is immaterial how this effect is reached, whether by calcification of tubercles, or fatty degeneration, or ossification, or cicatrization, or by solidification of fibrin, or any other pathological process, so long as we reach our desired object—namely, of drying up, so to speak, the softened or infiltrated portions of the lung-tissue.

I well know how settled the professional mind is on the incurability of phthisis, especially tubercular; and it is not without a feeling of misgiving that I venture to continue my assertions regarding the curability of phthisis. I am aware that such assertions will be charged to undue enthusiasm in a pet method, or to misguided judgment regarding the value of facts. Still I feel it my duty to say what I believe. It is not my purpose to theorize on the relation between the cause and the effect, although there must be room for all theories.

The profession, as a whole, accepts and rejects views as it sees fit. But facts are stubborn things, and are always acceptable to the profession, no matter what their particular interpretation may be. With this view a short description of some of the cases treated by my method is offered, in the hope that the profession may become convinced of its efficacy, and resort to it accordingly. I claim in no way perfection, or anything wonderful, but unless my judgment is utterly defective, these cases must convince the most conservative sceptic, that tubercle-cases of the lungs can be arrested to a degree hitherto considered absolutely impossible.

It may be well to state beforehand, that all the cases reported were more or less desperate ones; that to manage such patients is very difficult, sometimes impossible, and that even with the utmost caution these patients, especially the recovering ones, will commit follies almost incomprehensible, and utterly beyond the control of the medical adviser. But it will be seen that the effect of my treatment is uniform, regardless of the final result, the same in each case, and excluding any accidental improvements which are so common in these cases.

Mr. W. H——, merchant in New York; native of Yonkers; twenty-eight years of age; lost a brother and sister of consumption in 1876; had been sick for ten, and was compelled to give up business for two years. Had tried Colorado, Minnesota, and the South, outdoor tent-living, with injurious results; had been examined by Drs. C. P. Tucker, A. Clark, and A. Flint.

Examination denoted decided dulness at both summits; right side, comprising both upper lobes, with *bruit de pot fêle;* lower portion of right chest, absolute dulness to about the nipple. Auscultation on right side bronchial, with strong gurgling sound indicating a cavity of four by two inches; middle portion, broncho-vesicular; lower portion of chest, absence of sound; right upper lobe, subcrepitant râles with bronchial respiration. Pulse 124 and variable. Heart well. Digestion fair. The patient came under my treatment in October, 1876. In August, 1877, he went back to his business, four months sooner than I wished him to. His condition was then as follows: Dulness of percussion nearly the same, except the right lower portion, where it had entirely disappeared. Auscultation: The gurgling sounds of cavity had disappeared; cavernous respiration indicated the cavity smaller on summit, but had extended somewhat downward, caused by formation of a new cavity; respiration around it broncho-vesicular. In lower portions of right lung, normal vesicular respiration. Left upper portion respiration vesicular, with a very slight tubular timbre and prolonged expiration; lower portion normal. He was at that time re-examined by Dr. A. Clark.

The patient has remained steadily in business, working hard. I examined him again in January, 1879, when he had neglected himself somewhat. I then heard bronchial râles and moist crepitation on left side. It soon subsided, and he was hard at work when I last saw him in June, 1879. He is at present travelling in Europe. From August, 1877, to June, 1879, he had not missed a day in his business in the city, while he lived in Yonkers. Considering the large cavities, which of course cannot heal on account of the pyogenic membrane, and cause him to cough on exertion, he appears perfectly well from his looks and actions.

Mr. Herrm. B——, merchant, in 51 New Street, New York; native of Hamburg; twenty-two years old; had lost a brother from consumption in Madeira in 1871; was attacked several times by haemoptysis in 1875, for which he was treated by Dr. Pregitzer, of Staten Island. Not recovering, he consulted Dr. Schnetter, of New York, who sent him to Aiken, S. C., from where he returned much reduced. Dr. S.

then advised him to go at once to Pau in the winter, and to Davos, Switzerland, in summer. With the steamer ticket in his pocket, he came to me in October, 1876. His appearance was decidedly hectic; had night-sweats, and a pulse of 135 at rest. Percussion dull on both apices, much more on left than on right side, with cracked-metal resonance between third and fourth left ribs, and pains on percussion. Respiration bronchial, with subcrepitant râle, on both summits, on left side down to fifth rib, with cavernous whisper between third and fourth ribs, indicating a cavity of the size of a large walnut. He was not able to walk ten blocks, and could not retain his food. He was under my treatment from October, 1876, to June, 1877, when he sailed for Europe. Before he sailed Dr. Lellmann, physician to St. Francis' Hospital, New York, had the kindness to examine him, and although he was very much better than when I first saw him, Dr. Lellmann warned me not to be sanguine in my expectation of his recovery. The patient returned to New York in October, 1877, and re-entered business. He is a well-known member of the Produce Exchange. He finally became careless of himself, when an attack of hæmoptysis frightened him, and gave me a chance to perfect his cure. He has recovered so as to outwalk me at any time, dances all night, eats and drinks as he pleases; has been through serious business excitements, and broken his fibula, which confined him four weeks on his bed. He looks so well, and shows such vitality that he is laughed at by his friends when he says he is consumptive. The condition of his lungs is as follows: Percussion is moderately dull in both summits. Auscultation denotes a somewhat large vesicular respiration in the affected portions, with prolonged expiration. The signs of the cavity on left side have disappeared, so has his cough. His pulse is 60 to 70; he is very strong and has gained considerable flesh. His chest has become full and rounded, and he presents as perfect a recovery as can be realized only by the most sanguine expectation. Still, I am satisfied he would have died had not the hæmoptysis brought him back under my control in 1877; and I may mention that when I took him as a patient with the view of curing him, I was ridiculed by all his friends.

Frank W. T——, M.D., practising physician of New York, came to me in March, 1877. He had been examined by all the leading specialists of New York, and had been treated by Drs. Elsberg and Linoln for marked aphonia of two years' standing. He old me that these gentlemen found two tubercular ulcers upon the vocal ligaments. Examination of ung denoted marked dulness in both summits to bout fourth rib, and an exudation of two inches in ight pleura, over which auscultation denoted a soft repitation, indicating a not fully reabsorbed pneuonia. Respiration in both upper portions bronhial, with mucous and subcrepitant râles. Pulse 20, digestion entirely out of order, very weak, and hort of breath. Two weeks after I treated him his phonia left him, when he failed to appear. I found im in his office very sick. He had taken nitrous-xide gas and morphia. I managed to get him out gain, but he was a very irregular patient, and I lost ight of him until September, 1877, when he came ack much reduced and weaker. He then began reatment in earnest, and improved steadily, so that e could walk daily to my office during the whole inter, which he could not do previously. In June, 878, he went to spend the summer on a farm, with ie direction to return in September to complete his ecovery. That was the last I saw of him. I am fearful that he feels so well that he considers no further treatment necessary.

John M——, architect, a patient of Drs. John L. Campbell and James L. Little, presented a case of pleuritic exudation of about four inches in left pleura, dulness over whole left lung on right side to fourth rib. Auscultation showed the varieties from cavernous gurgling to dry, moist, mucous, and metallic râles. Both tympani were destroyed by tubercular ulceration, with ulcers on tongue and pharynx. He had also three fistulæ-in-ano, from which he suffered very much. I treated the case, by special request of Dr. Campbell, from September, 1877, to March, 1878. The patient made such favorable progress that Dr. Little sent me a note of congratulation. An abscess in the lungs broke on the 10th of December. This completely upset him; still he rallied again, walked over three miles per day, until February, when another abscess broke, and two weeks after that another, which completely exhausted him. He died very easy. Post-mortem was decidedly refused. This case was an utterly desperate one, with no chance at all, but it showed the effect of treatment, nevertheless, as the medical gentlemen mentioned above can testify.

Mr. C. A. M., merchant of New York, 22 years of age, had been treated some time by a French physician when he was examined by Dr. A. Clark, who pronounced his lungs affected, and recommended the South. He was also examined by Dr. Metcalf, who concurred in the same opinion. The patient, therefore, went to Asheville, N. C. This was 1877–78. He returned very much sicker. I saw him in May, 1878. Percussion was dull, more or less, over the whole of left lung front—moderately dull in right summit to about third rib—resonance on back about even on both under portions. Auscultation denoted ronchi of cavernous character front and back on left side—some portion almost entirely devoid of any respiratory murmur, while portions between them gave bronchial râles, and subcrepitant râles over the whole of left portion in front. There was some vesicular murmur audible on lower portion of back, but of a moist character. Left upper side subcrepitant râles on summit, lower portion normal; expiration a little sharper. Pulse 128 at rest; decidedly hectic; parents both healthy and living, but several brothers delicate. Patient could walk but very slow and with difficulty. As the case was decidedly a desperate one, and liable to die at any time, I took the precautionary measure to have him re-examined by one of the most distinguished physicians of New York, who gave his opinion that the patient was beyond the hope of any possible recovery. I then treated the case with the following result: for the first two months he made no perceptible progress, except that he obtained better sleep and became livelier. In September his pulse began to fall, and he improved visibly. In order to reach my office daily, he had to travel twenty-four miles by railroad and a mile to walk. He improved so that he walked three or four miles daily when at home, besides his thoracic exercises. His pulse began to fall from 76–78. In February it began to rise somewhat, and the patient complaining of soreness in his left thorax, made me suspect an abscess ready to open, and he removed temporarily to the Windsor Hotel. After a few days the abscess opened, and he discharged a large quantity of pus. To my surprise this did not affect him so seriously as it generally does, but he soon felt so much better that I permitted him to go home again. Pulse back again to 78. The large cavity left could easily be diag-

nessl, which, with the already existing smaller cavities, comprised an area from the clavicle down to the nipple. The tissues existing between these cavities I hoped to save for cicatrization. The patient meanwhile, remained about the same, not well enough to do business and too smart to do nothing, the right lung progressing well all the time. Spending the summer with me in Nantucket, Mass., he left a week in August for New York City to meet his father, who had just returned from Europe, and to have a good time generally. He returned to Nantucket somewhat used up, but still his physical signs were about the same; pulse 96. Thinking that I could make a change for the better I allowed him to travel over the White Mountains, regardless of weather, which he did in September, consuming about three weeks. He enjoyed his trip very much, but returned changed for the worse. His lips and nails, which were rosy and bright, looked bluish; his pulse 112, and very feeble. Examination showed that the cavities in the left lung had coalesced. Right lung in perfect order; respiration vesicular throughout and dry; only in upper portion respiration prolonged and audible. The patient travelled his twenty-four miles every day to reach my office; his pulse is 80 in bed; 104–112 in daytime; appetite and digestion perfect. The case is an extremely painful one, demonstrating the good effect of treatment in one lung and its utter helplessness in the other one. This patient finally succumbed to the disease.

Mr. Alex. W——, bookkeeper in Bank of Lansingburgh, 26 years old. I saw the patient while in Albany. He had been sick about two years, trying in vain different modes of treatment. Besides being lung-sick, he had chills and fever for two months, for which he had been in Brooklyn, but failed to get rid of them. I saw him in May, 1878. Examination showed the left upper lung very dull on percussion. Respiration bronchial, with mucous râles. Subcrepitant râles in lower left lung. Right lung less dull on percussion, with some mucous râles, but with subcrepitant râles in both upper lobes. Pulse 145; very weak. Epigastrium painful, abdomen hard and dull, digestion completely out of order, severe night-sweats; hectic, with bluish lips and nails. I ordered a dose of sulphate of soda, followed next day by a dose of the juice of twenty lemons, with hot-water sheets applied an hour previous to the chill. This arrested his fever and chills at once, and he came to New York. His pulse was 140, and he was so weak that he was unable to walk four blocks. His cough and looks alarmed the guests and landlord at the hotel in Nantucket, who thought he had been brought there to die. He soon picked up, however, and in February, 1879, he walked over 200 miles. Although not quite well he left me in June, with the understanding to spend the summer in Nova Scotia, at the seashore, instead of which he remained at home in Lansingburgh, doing business. The result was a return of the chills and fever, for which he was in New York a few days ago to consult me. I advised him to go home again to apply the hot water until the epigastric pain had gone. Of course, he does not look so well as he did in the spring, but, with some attention on his side, he will soon make up again. His pulse has been all along 58 to 60, when quiet; since the fever, it has, of course, been higher, varying from 80 to 96.

Mr. Geo. W. Sh——, from Albany, came to me, through Drs. Bailey and Curtis, in June, 1878. Examination showed a moderate dulness of both summits to third rib on right and fourth rib on left side, with subcrepitant râles. Pulse 80, no complications. This case made very rapid progress, gaining six pounds in weight, under somewhat severe exercise, in two months. Instead of remaining with me until Christmas, when I promised to dismiss him as cured, he felt well enough to discharge himself.

Mr. J. Watson A——, 30 years of age, from Fishkill, N. Y., a merchant, came under my treatment in August, 1878. He had a very moderate dulness over both upper lungs, with bronchial mucous râles and moist crepitation. Pulse 76. This, I considered, was quite a curable case. He left me suddenly after two months, just when the case worked to my full satisfaction. I did not see him again until this last summer, when he had apparently failed very much. Since October 1st he has been my patient again. The dulness now is quite perceptible, his pulse 101 to 112, and I am apprehensive of the formation of an abscess. Auscultation denotes subcrepitant râles over both upper portions. Respiration decidedly bronchial, with occasional mucous râles. I shall report the result of my treatment hereafter.

Miss H——, from Brockport, N. Y., aged 20, was sent to me by Dr. Braman, in August, 1878; marked dulness in both apices as low as fourth ribs, with bronchial respiration and subcrepitant râles. Not able to retain any food; very feeble and nervous; pulse over 100. She recovered so quickly that she could walk two miles without difficulty. After six weeks I ordered her to exercise her respiratory muscles more actively, which resulted in serious pains in back and abdomen. I then discovered that she was suffering from prolapsus uteri with antroversion, and which she had hidden from me for unknown reasons. As this arrested my treatment, and she preferred her brother-in-law to the specialists recommended by me, she left for home. I have heard that she died a few months since.

Mr. A. R. McM——, merchant and banker, from Toronto, came to me in August, 1878, through Dr. Walsh, of Michigan. Had been a consumptive in valid for ten years, under treatment of Dr. Phillipps, of London, Eng. Had been in Egypt, Madeira, Mentone, and Western America, with temporary benefit, but had failed rapidly for the last two years. fifty-two years of age; presented a strongly marked hectic habitus. Examination, left side, denoted decided dulness to fourth rib, with bronchial and irregular respiration and subcrepitant râles; right side, marked dulness to fifth rib, with *bruit de pot fêlé* under clavicles, which stood out higher than an inch. Auscultation gave strongly-marked cavernous respiration under clavicle, surrounded by bronchial and irregular respiration, with wheezing noises; occasional mucous râles; amphoric voice; pulse intermittent every fifth or seventh beat—irregular, but not higher than 72 to 76; heart appeared normal. Patient was very weak; chest sunk and flat. After three months his pulse became perfectly regular. He left me in May to spend the summer at Rye Beach. He intended to return to business this fall but by my advice and that of his friends, will spend this winter still under my observation. His condition is now: Chest full and developed; walks ten miles up and down hill as straight as an arrow, without unusual fatigue; pulse 60 to 64. Examination of chest denotes moderate dulness on both summits. No marked signs of the cavity left. Respiration established evenly in both points, with a broncho vesicular character and prolongated expiration. No râles. Since August he has occasional spasms of cough seemingly caused by irritation of throat, but may be

due to reflex irritation also. He managed to get his digestion out of order at Rye Beach, without apparent injury to his system. I expect to dismiss him in the spring a fully recovered case—which he is nearly now.

This necessarily short report of these few cases may suffice to illustrate the nature of the affections in question. It will be seen that most of them have been examined and treated by the most accredited specialists in the country, and there can be hardly any doubt as to the seriousness of the cases, none of which had any chances left by the usual routine treatment. Even if I had lost all these cases, which fortunately I have not, a uniform effect of my treatment is apparent in any of them, as I take patients as they come, and I have to bear up against the fact that the quick recovering ones leave me before I get a chance to finish them, while the failing ones invariably remain with me until death. This fact makes my full recoveries less than they would be otherwise.

As already stated, the treatment cannot be expected to accomplish miracles, but it is offered as one which brings about gratifying results. The expansion of the lungs by the active and varied exercise of the respiratory muscles, is comparatively simple. The difficulty is in keeping it up in a systematic and methodical way, with a determination to accomplish the ultimate result. It requires the utmost patience and perseverance on the part of the patient, and the physician should have him under complete control. The same may be said regarding diet, but in a much greater degree. The patient's diet must be studied day by day; he must keep a diary of his meals, and give a daily account from his written record of the time of eating, the amount and variety eaten, and of any unusual symptoms which may be referred to imperfect indigestion. Under such training, the system soon makes known its wants, and the discriminating physician acts accordingly. But this, of course, cannot be learned except by a study of individual cases and by the use of that common sense which comes of extended experience and careful observation.

Progress of Medical Science.

Nerves in the Marrow of Bones.—M. Rémy has examined microscopically the marrow of amputated bones, by means of chloride of gold, and claims to have discovered nerves. Some of them contain myeline, and are of small size; others are fibres of Remak. They are very numerous, follow the course of the vessels, and are, in all probability, vaso-motor.—*La Tribune Médicale*, January 1, 1880.

Inflammation of the Internal Coat of the Vessels in Tubercular Meningitis.—In 1867 M. Cornil demonstrated the blocking, with fibrin and white blood-globules, of the vessels of the pia mater running through tubercles. Further observation has convinced him that the lesions of the vessels in tuberculosis do not consist entirely of inflammation of their sheaths and external coats, but that there is also a special inflammation of the tunica interna, and to this tubercular endarteritis and endophlebitis he has called the attention of the *Académie des Sciences*. This more or less thickened membrane, situated in the middle of the tubercle, is formed of round, elongated, or angular cells, all provided with small rounded nuclei. Approaching the lumen of the vessel, some very large cells are found, giant-cells in fact, which in this disease are only found in the internal vascular coat. As a practical conclusion, M. Cornil advances the opinion that these alterations tend to prove the infectious nature of tuberculosis, the contagion being evidently carried to the tunica interna by the poisoned blood.—*Le Courrier Médical*, January 3, 1880.

Changes in the Cutaneous Nerves in a Case of Vitiligo.—The pathological anatomy of vitiligo, especially the changes occurring in the cutaneous nerves, has hitherto received but little attention; a fact which will increase the interest in the following observation reported by MM. Leloir and Charrier. The patient was a man, twenty-three years of age, who had been attacked three years before with vitiligo, and who, during infancy, had suffered from various skin affections, such as impetigo, pemphigus, psoriasis, etc. Eight years previously he had contracted syphilis; five years afterward ulcerations appeared on the penis, and their vicinity was shortly marked by large characteristic spots of vitiligo. These spots, surrounded by deeply pigmented circles, increased in size, and new ones appeared in consequence of the irritation of the skin by the application of medicinal substances. This led M. Fournier to believe that the affection was of nervous origin. A small piece of skin was removed from a three year old patch, situated on the lower portion of the abdomen, and submitted to MM. Leloir and Charrier for examination. They found that a large number of the nerve-fibres were greatly changed, presentiug distinctly the lesions of nervous atrophy. These changes pointed to the fact that there had been a slow degenerative process. Besides the nervous lesions, it was also shown that the epidermis was greatly thinned; the papillæ had entirely disappeared, and the corneous layer alone remained. Is this an exceptional case, or are these lesions always present in vitiligo? If they are present in all cases, this disease resembles other trophic troubles of the skin—for example, anæsthetic leprosy and certain forms of pemphigus.—*Le Courrier Médical*, December 27, 1879.

Arthropathy of Locomotor Ataxia.—Some years ago M. Charcot described a peculiar lesion occurring spontaneously in the course of locomotor ataxia, frequently at the very beginning of the disease, to which he gave the name of "arthropathy of ataxia." These lesions, accurately observed by him at *La Salpêtrière*, were afterwards recognized by Westphal in Berlin, Mitchell in America, and Rosenthal in Vienna. These observers differed only in their interpretation of the nature of the affection, M. Charcot believing it to be a clinically distinct affection, while the others considered it only a form of dry arthritis. M. Charcot has given the clinical and pathogenic reasons which induced him to think this affection a direct result of the changes in the spinal cord, and not an accidental and concomitant lesion. An analysis of the bones of an ataxic subject suffering from arthropathy, made by M. Regnard, and reported to the Academy of Sciences, would seem to support the positiou taken by M. Charcot. It shows that the bones, in this disease, undergo great changes in their composition, similar to those observed in subjects of osteomalacia. These changes are not confined to the extremities of the bones as in dry arthritis; the bone becomes fatty through its entire length, the earthy salts disappear, become very brittle and break with the least exertion, giving rise to the spontaneous fractures of ataxia. The arthropathy of ataxia, then, according to M. Regnard, is very similar to osteomalacia, or to

the c[illegible]s steatosis of Jones, diseases in which we sometimes meet with as much as twenty-nine per centum of fat, the phosphates being reduced to twelve or even to seven per centum.—*Le Courrier Médical*, December 27, 1879.

Repair of the Blood after Acute Diseases.—The following is a short résumé of a lecture on this subject given by M. Hayem.

The evolution of the blood, arrested during the course of acute diseases, recommences from the moment of defervescence. The manufacture of red blood-globules is accomplished by means of a new production of hematoblasts, viz., minute red blood-corpuscles. In observing this phenomenon, it is necessary to distinguish acute diseases of short duration and rapid recovery from those of slow course and protracted convalescence. In the former class, the production of hematoblasts accompany, or closely follow convalescence, and a large number of these elements suddenly appear in the blood; but, as they are rapidly transformed into red globules, their accumulation in the blood, after having once attained the maximum number, is relatively short. In cases of the second class, the production of hematoblasts is more tardy, following one or more days after convalescence; then the number of the new elements, their formation not ceasing, is, for a long time, greater than that of the transformed globules. Their accumulation seems to be accomplished by successive "*bonds*," and the maximum number is not reached for one to three weeks. This repair of the blood is analogous to that taking place after hemorrhages, especially after long-continued bleeding. In consequence of this production of new elements, under the form of hematoblasts, and afterward of blood-corpuscles, the blood of convalescents contains, for a variable period, incompletely developed red globules, which reduce below normal the average amount of coloring matter contained in the red corpuscles. *Le Progrès Médical*, December 6, 1879.

Inhalations of Bromide of Potassium in Pertussis.—Dr. Körner, of Trebnitz, has for some time treated all his cases of whooping-cough with inhalations of bromide of potassium, and states that they all recovered completely in a relatively short space of time. He uses generally a four or five per cent. solution, and makes the patient inhale about twenty grammes (ʒv.) three times a day. He says: "After the first few inhalations a very decided improvement was noticeable, and in from three to five days the alarming suffocative attacks ceased, and the children expectorated easily. After a few days more, the whooping-cough, had as a rule, disappeared. The children took the inhalations readily, much more so than they did medicine." Dr. Körner insists on the importance of administering the inhalations properly, and on the necessity of the physician supervising them himself, at least in the beginning.—*Allg. med. Cent. Zeit.*, Nov. 19, 1879.

On the Action of Pyrogallic Acid.—Pyrogallic acid, which has latterly been recommended as a substitute for chrysophanic acid or chrysarobin, is, according to Dr. Neisser, even when employed externally, one of the most powerful poisons. He was led to investigate the action of the drug by the death of a robust man, who was under treatment for psoriasis universalis in the dermatological clinic in Breslau. After some preparatory treatment, chrysarobin in the form of a twenty per cent. salve of the ext. rhei spirituosum had been applied, in the usual way, to one half of the patient's body, and a ten per cent salve of pyrogallic acid to the other half. Six hours afterward the patient had a violent chill with nausea, vomiting and marked collapse. He rallied from this attack, but had a second one forty hours later, which terminated in coma, with great lowering of the bodily temperature. Death took place on the fourth day after the application of the salve. The urine passed during this entire period amounted to only 1,600 cctm., and the last passed presented the highest degree of hæmoglobinuria. At the autopsy the blood was found to be of a dirty, brownish-red color; microscopically, it presented a large number of perfectly colorless stromata and many fragments of corpuscles. The kidneys were bluish-black in color, and the tubules were filled with a substance similar to that found in the urinary sediment.

Neisser first demonstrated the innocuousness of chrysarobin by injecting very large doses of different preparations of rhubarb under the skin of rabbits, and then showed, by analogous experiments, that pyrogallic acid, so used, is poisonous. When a moderate dose was injected, it caused a chill, dyspnœa, tremor of the extremities and lassitude, and the animal either died in the first or second attack, or recovered after experiencing several slighter paroxysms. The urine passed during the first paroxysm presented distinctly the characters of hæmoglobinuria; the blood presented the above characters, and the renal tubules contained numerous hæmoglobine casts. When larger doses were administered the animals died in the first paroxysm, and the blood presented the same characters—viz., discoloration and destruction of the blood-corpuscles, but hæmoglobinuria was not developed. When still larger doses were used (two grammes for one kilo. of weight), death usually took place within two hours. In these cases also hæmoglobinuria was wanting; and the blood was of a black color, and sometimes of a chocolate or jelly-like consistency, but it did not present the remains of destroyed corpuscles. These effects of pyrogallic acid, on men and animals, are ascribed by Neisser, first to the affinity of the acid for oxygen in the presence of alkalies, and second to its consequent decomposition; these reactions can be produced and studied as well outside of the body. The acid, when taken into the blood, destroys more or less of the red corpuscles; the hæmoglobine is dissolved in the plasma of the blood, and the remains of the corpuscles are suspended in it and reduced to fragments. The hæmoglobinuria resulting from this destruction, cannot, according to the experimenter, prove fatal through the anuria consequent upon the obstruction of the renal tubules, because this anuria is too brief to permit of a fatal accumulation of the constituents of the urine in the blood, but it can by the retention in consequence of this obstruction, of the pyrogallic acid in the body, and the prolonged exposure of the blood to its destructive action. He does not attempt to account for the development of the obstructing pigment-casts in the renal tubules. Transfusion with simultaneous venesection would be the rational method of treating poisoning by pyrogallic acid. In the earliest stages the induction of active diuresis to keep the urinary canals open would also be indicated. Dr. Neisser suggests that his experiments prove that pyrogallic acid should not be applied to a large portion of the body at once. He thinks that its use should be confined to the head and face, and that the innocuous chrysarobin should be preferred for the trunk.—*Berliner klin. Wochen.*, Nov. 24, 1879.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 21, 1880.

THE ABUSES OF MEDICAL CHARITY.

It is hardly necessary to excuse the interest which is now being taken in the question of the abuse of medical charity. In fact, in view of the enormity of the evil, and of its widespread character, it is a wonder that it claims such a comparatively small amount of the time and attention of medical men.

Possible reasons for this are, that the older men in the profession are, pecuniarily speaking, beyond the reach of the bad influences of the system, and the younger men are apt to look upon the present condition of things as inevitable, and past remedy. As a marked evidence for reform, however, it is gratifying to notice that the sentiment of the younger men is beginning to change, and in various sections of the country the abuse of medical charity is being discussed in a way that promises some practical result. The matter of making a living by his profession appeals to him with terrible earnestness. Year by year, with the increased competition going on around him, he finds that his chance for success is becoming less and less. He cannot prevent the new men from dividing up his living, and he is consequently compelled to enlarge the field of his struggle, and to look after what was heretofore considered the waste places. The idea of throwing away services for the sake of being called charitable, of struggling the best years of one's life for a bare subsistence, and, in the end, leaving a family dependent upon some widow and orphan society, is beginning to lose its romance. The necessities of the hour look beyond this. There is nothing that gives a man a better chance in a race for bread than to know that his breathing is not impeded by a full stomach. It is hardly complimentary to the younger practitioner to liken him to such a bread-winner, but it is necessary to do so in the cause of truth. Hence, we can appreciate the earnestness of his efforts for reform.

We agree with him, and with all others who have given attention to the subject, in saying that the abuse of medical charity is beyond all reason, and that the most radical measures are called for. The evil, far from abating, is on the increase. Dr. Dana, in a very suggestive and instructive paper on this subject in the present issue, gives some interesting statistics concerning this point. The ratio of increase of medical paupers in Birmingham, compared with the general increase of population of that city, is a striking fact, and will doubtless find its parallel in large cities in this country. In this city there is such a premium on medical pauperism, that the latter is becoming respectable. It is considered a smart thing to dodge into the college clinic, into the dispensary, or out-patient department of a hospital, and get the opinion of "a head doctor" for nothing, and this from people who can afford to pay. The story of the dispensary patient who complained that she was kept waiting while she was paying a dollar an hour for her carriage at the door, has its counterpart in the experience of every dispensary physician and clinical attendant. We have in mind the landlord of a doctor who called upon the latter for advice at a dispensary, and when the service was refused, said that he never paid for what he could get for nothing. But it is useless to multiply examples, or to prove a point already well established. The time has evidently come for the profession to do something to protect itself, and we are pleased to learn that the task is being undertaken with a freshened vigor, which promises tangible results. In Chicago and in Philadelphia large and earnest meetings of medical men discussed the subject in all its varied phases, and committees have been appointed to draw up a plan of action which shall tend to reconcile the conflicting interests of the colleges which must have clinical material, and the struggling medical men who must have practice. As in other cities, Chicago and Philadelphia are overrun with medical charities. In this city particularly, if the facilities for dispensary treatment, for hospital accommodation, and for clinical demonstration, are not curtailed, the practitioners who attend the middle and lower classes, and who are content with ordinary fees, will be left entirely out of the race.

Various plans have been suggested to remedy the evils. The payment of small fees has been tried with some benefit, but this is open to the objection that the people will get into the habit of supposing that the services are worth no more than the normal charges made. The provident plan has been discussed with much earnestness by the medical profession in Great Britain, but the practical results thus far have not been as satisfactory as was anticipated. In this country the idea of the establishment of similar institutions is beginning to assume a tangible form, and will doubtless ere long be an accomplished fact. But

before the latter can be realized, much has to be done in reforming the present free dispensary system and in correcting the abuses of the college clinic. How this may be accomplished will be the subject of future discussion in these columns.

A FOREIGN STIMULANT.

A new edition has recently been issued of Johnston's "Chemistry of Common Life." It is edited by Mr. A. H. Church, who has made additions that will bring what used to be a standard work into favor again. Aside from its general merits, there is no book which brings together the facts in regard to the narcotics and stimulants used by the human race, in a more thorough and pleasing manner. Its republication has attracted attention to some of the statements therein made concerning the use and properties of these drugs.

There is no one of them which is so likely to strike the attention, on account of its reputed virtues, as the Peruvian coca. This coca consists of the sun dried leaves of the *erythroxylon coca*, a shrub growing wild upon the Andes, as well as extensively cultivated by the natives. It bears some resemblance to the tea-plant in appearance, odor, and effects. It has been used from time immemorial by the South American Indians, who are passionately fond of chewing its leaves. These they carry in a pouch at their side, along with a bag of pulverized quicklime, or ashes, with which they sprinkle the leaves, in order to bring out their full flavor and strength. The leaves are chewed until the juice is extracted, when the quid is spit out. Part of the juice is swallowed.

The most extraordinary accounts have been given by travellers of the virtues of this herb. It is said to take away the sense of hunger, and greatly to diminish the necessity of food; it relieves the muscular fatigue that comes of hard work or severe exercise, and enables persons to prolong this to a great extent. When taken in large quantities, it increases the activity of the mind, and produces a general exhilaration amounting sometimes to mild delirium. It has an extraordinary property of preventing the dyspnœa usually felt when climbing too high altitudes. Two hundred years ago the poet, Cowley (who was also a physician and botanist), in a poem on plants, wrote of this particular virtue:

> "Three leaves supply for six days' march afford;
> The Quitolta, with this provision stored,
> Can pass the vast and cloudy Andes o'er."

The Indian runners travel forty miles a day, eating only a little roasted maize, but chewing frequently the leaves of the coca. So valuable and remarkable a property does the plant have, that its introduction into Europe has been strongly recommended as a help to the overworked and underfed working-classes.

Some of the above statements have been made by physicians and reputable men; they are, at all events, endorsed by the editor of the recent edition of the "Chemistry of Common Life." If the drug has in fact any such properties as are described, it deserves more attention than has been given it. For, in these days of pedestrianism, bicycles, and athletic tournaments, something that will prevent tissue waste and muscular exhaustion would be extremely popular.

We have failed to find any very satisfactory experiments in confirmation, or otherwise, of the alleged properties of the drug. In 1876, Sir Robert Christison procured some of the leaves and tried them upon himself and fifteen of his friends. His plan was to walk until nearly exhausted by fatigue and hunger. He would then take from one to two drachms of the leaves. He found in each case that his fatigue was removed, the sense of hunger gone, and he was able to continue his journey with an elasticity and ease that surprised him. The leaves used by most of his pupils were weak and of poor quality. Among those who used only good specimens, the results agreed with those of Sir Robert's. He found that the pulse was not increased so much as when exercising without the drug, the perspiration was not affected, and the solids of the urine were lessened. The mind was not affected at all, nor was the appetite or digestion impaired. In the same year, however, Mr. G. F. Dowdeswell made a number of experiments upon hospital patients, and with entirely negative results. He gave his cases coca in large quantities, at all hours, without producing any sensible effects. Earlier experiments are equally conflicting and unsatisfactory. There are none recorded, however, in which similar trials to those of Christison's were made, and the difficulty of obtaining pure samples of coca make many of those tests with negative results unreliable.

One of the active principles has been isolated, and is found to resemble theine in chemical composition. This, with other facts, makes it probable that the plant's real properties do not differ greatly from those of tea. Thus, even its power to relieve the dyspnœa of high altitudes belongs somewhat to tea; Alpine travellers find that there is nothing so helpful or refreshing.

Nevertheless, so much stronger properties have, for a long time, been ascribed to coca, that we cannot consider the matter at all settled, and we must wait for further experiments.

EAR-COUGH.

Several cases, recently reported, of ear-cough, ear-sneezing, vomiting, and hiccough, call attention to a peculiar reflex disturbance that a few years ago excited much discussion. One of these cases was that of a woman who for years had been treated for chronic bronchitis. An increasing deafness finally drew attention to her ears. These were found to

contain large accumulations of inspissated cerumen, upon the removal of which the cough disappeared. In another case, a man was suddenly attacked with violent and incessant sneezing, which nothing could stop. It continued for two days until the man finally fell down exhausted and unconscious. When revived he complained of loud noises and great pain in both ears. They were found to be full of cerumen, with the tympana acutely inflamed; treatment directed to the ears cured the sneezing.

Some of the phenomena of ear-cough were described more than a hundred years ago. Any thorough attempt to explain the physiology of the matter, however, was not undertaken until about the year 1870, when quite a controversy took place in the English journals. Ear-cough was then asserted by some to be due to an irritation of the auricular branch of the pneumogastric, or Arnold's nerve, which induced a reflex irritation in the fibres of the pneumogastric, or more especially, perhaps, in the superior laryngeal, the nerve furnishing sensation to the larynx. Arnold's nerve is generally described as supplying the integument at the back part of the pinna, the auditory meatus being supplied by filaments from the temporo-auricular branch of the fifth. It was thought, however, that occasionally the auricular nerve sent branches into the meatus and, in such case, an irritation of it caused the reflex symptoms. Mr. John Wood asserts that he has occasionally seen this nerve perforate the auricular cartilage, and has traced it into the meatus. Although this may still furnish the best explanation of the symptoms, it is not a perfectly satisfactory one. It does explain why the cough does not occur when the nerve is irritated in other parts of its distribution, nor does it explain the reflex phenomena of sneezing in which we may suppose that the fifth ought to be involved. It involves also the hypothesis that the auricular nerve always has the particular distribution indicated when the symptoms occur.

It has been asserted, therefore, that all these symptoms are due to an irritation of the branches of the auriculo-temporal, the nerve which always supplies the meatus. Lockhart Clarke has shown that the nucleus of the pneumogastric is intimately connected with the base of the gray tubercle of Rolando, from which the sensitive root of the fifth arises. He has suggested that the irritation of the fifth might be transmitted to the vagus through this connection. However that may be, it is easier to suppose that the ear-sneezing is due to a primary irritation of the fifth in some way, as we know that to be the usual mode of producing the phenomenon. Irritation of stray filaments of this nerve are thought to cause sneezing in other cases. Thus, a sudden exposure of the eye to a bright light will sometimes bring on an attack of sneezing; and it is known that the nasal nerve occasionally sends filaments to the ocular conjunctiva. It is suggested that nerves are more irritable when thus distributed abnormally.

The question is by no means definitely settled, and it might be worth while for physiologists to make it the subject of further study.

TAXING DOCTORS FOR A LICENSE TO PRACTISE.

Some persons are making a strong effort in Washington to pass a bill compelling doctors to pay $50 per year for the privilege of practising medicine. This seems very much like putting on the last straw. The doctor now attends to all the city poor gratuitously, furnishing his services at the hospitals and dispensaries. This would cost the city thousands of dollars, if properly paid for, as is every other thing furnished to paupers, from butchers' meat to religious consolation. He is obliged to fill out, gratuitously, birth-certificates and death-certificates, both of which imply extra labor and special knowledge. He is expected to serve, without pay, on all kinds of medical boards, health boards, and charitable boards. Indeed, his advice and help are wrested from him, with no return, on every occasion possible. The fact that all these services are contributed willingly, does not destroy the obligations they confer, nor justify governmental authority in putting a heavy annual tax on him for his labors.

EXAMINATIONS FOR COLOR-BLINDNESS.

The examination of employees on railroads and vessels for color-blindness is becoming more extensively adopted as its importance becomes better known. The Boston and Hingham Steamboat Company, and the Boston and Lowell Railroad Company, now require all their employees to be examined for color-blindness by an expert.

In this city, all the employees, numbering over seventy, on the ferryboats of the Pennsylvania Railroad Company, have recently been examined by Dr. White, one of the Marine Hospital surgeons at this port. Among these latter one man was discovered to be almost a typical case of color-blindness, being unable to match the worsteds at all. The Pennsylvania Railroad Company intend to have all their railroad employees, who occupy positions requiring a knowledge of signals, to be examined.

It is to be regretted that there is a tendency in some quarters to have these examinations made by laymen, either in order to save expense, or out of an ignorance of the necessity of special knowledge on the part of the examiner. Thus, it has recently been resolved by the local steamboat inspectors that they will test the pilots for color-blindness. This is, perhaps, well meant, but it is an unwise thing to entrust the matter to persons not trained in physical examination nor accustomed to weigh clinical evidence. There are about ten thousand pilots altogether in

this country. At a moderate estimate, two per cent. of these are color-blind. The importance of having this large proportion carefully eliminated can be readily understood.

Reviews and Notices of Books.

TRANSACTIONS OF THE TENTH ANNUAL SESSION OF THE MEDICAL SOCIETY OF VIRGINIA.

These Transactions are published in the January number of the *Virginia Medical Monthly*. An advantage gained thereby is, that they are out much earlier than is usual for such publications. There are a number of excellent papers in the present volume. The annual address by the president, Dr. L. S. Joynes, urges the value to the profession of medical societies, and the importance to the public of a State board of health. A very useful paper by Dr. E. T. Robinson is on the subject of the Recent Advances in Chemistry, Pharmacy, Materia Medica, and Therapeutics; Dr. Geo. B. Jennings reports Advances in Obstetrics and Diseases of Women and Children; Dr. Wm. H. Bramblett, Advances in Practice of Medicine; and Dr. Samuel K. Jackson, Advances in Hygiene and Public Health. Dr. H. P. C. Wilson describes an antithermic shield, which he finds useful in connection with Paquelin's thermo-cautery. Dr. J. Marion Sims, by invitation, contributed a paper on Abscess of the Liver, in which he described the case of Dr. E. S. Gaillard. A paper on Diphtheria, by Dr. A. M. Fauntleroy, gives some practical clinical reflections on that disease. Several other papers of less practical interest complete the volume.

DICTIONARY OF THE GERMAN TERMS USED IN MEDICINE. By GEORGE R. CUTTER, M.D. New York: G. P. Putnam's Sons.

A GERMAN-ENGLISH medical dictionary has long been a desideratum with physicians interested in German medical literature, and by such this little work of Dr. Cutter will be warmly welcomed. It is more than probable, however, that this feeling of satisfaction will, after a short use of the book, be slightly tinged with one of disappointment. A dictionary, to be of much use, must be full and exhaustive, and it cannot be claimed for this one that it more than approaches exhaustiveness, although it contains in the neighborhood of fifteen thousand words, which at first sight seems a large showing. While we must admit that we have been, to a certain extent, disappointed with Dr. Cutter's book, we do not, however, wish to be understood as condemning it. As far as it goes, it is really excellent. The number of words given is large, the definitions are clear, concise, and as far as we have seen, correct, and the general form of the book, as regards size, type, and paper, is very good. The student of German will find it a most convenient addition to the appurtenances of his writing-table. He will, at all events, find it to contain the great majority of the words he will have occasion to look for, and though some will be wanting, he will be much better off than when he had only the ordinary lexicons to consult. He will then undoubtedly join with us in regretting that the author, whose ability is too well known to require any testimony from us, did not aim to make his book as thorough as the present state of medical knowledge would permit.

TRANSACTIONS OF THE MEDICAL ASSOCIATION OF THE STATE OF MISSOURI, at its Twenty-second Annual Session held in Columbia, Mo., May 20 and 21, 1879. St. Louis: Mc Cormick Nixon & Co. 1879. 8vo. 144 pp.

Dr. L. W. SCHAEFFER'S address, as President of the Association, discusses the two following questions in an able and masterly way. "1st. What is the value and what are the dangers of popular scientific education? 2d. What can each one of us do at home for the benefit of the medical profession at large, and how can we cause the people to respect the regular profession and scientific medicine even more highly than they do now?" Dr. E. Borck follows with a "Report on the Progress of Surgery." The article on "Growths in the Larynx, the Importance of their Early Recognition," by Dr. C. A. Todd, shows the necessity of an early diagnosis, to the end that treatment may be commenced before it is too late to effect a cure. The much discussed question of the value of an "Absent Patellar Tendon-Reflex" is taken up and discussed by Dr. C. H. Hughes, who also describes an "Improved Æsthesiometer." Dr. Lutz's paper on "Epithelial Cancer" contains many good woodcuts of the disease. Dr. Michel has a very long and interesting paper on "Purulent Ophthalmias and their Treatment," in which he enters into the pathology, causes, and treatment of the various forms of the disease. The articles by Drs. Steele, Dickinson, and Engelmann are of interest. A list of officers and members, with the constitution and by-laws, complete a very readable and excellent volume of "Transactions."

TRANSACTIONS OF THE INDIANA STATE MEDICAL SOCIETY, 1879. Twenty-ninth Annual Session. Indianapolis: Baker & Randolph. 1879. 8vo. 225 pp.

This little volume contains many articles of interest to the medical profession. The President's address, by Dr. B. Newland, on "The Relations of Legislation to Sanitary Protection," is well written and strongly advocates the formation of a State board of health. Dr. G. L. Andrew, in an article on the "Rational Treatment of Dysentery," speaks in favor of the use of ergot, and says that he has used it with a great degree of success. He also gives a brief résumé of the various methods of treatment of the disease, and enters into a discussion of its origin. Dr. E. W. King has collected the "Statistics of Placenta Prævia" from the practice of physicians in the State. One hundred and twelve cases are given and analyzed. On the subject of "Immediate Placental Delivery in Natural Labor" Dr. E. S. Elder says that we should endeavor to have the placenta delivered as soon as possible after the birth of the child, as it lessens the chances of hemorrhage, hour-glass contraction, uterine inertia, adherent and retained placenta, etc. Dr. R. E. Houghton narrates "A Case of Fracture of the Cervical Spine," and advocates an operation to remove pressure on the spinal cord and hasten recovery. Several other papers on various subjects are included in the "Transactions," but want of space will not permit us to enter more fully into detail. The book is gotten up in a handsome manner and reflects credit on the Society.

FIRST LINES OF THERAPEUTICS, as Based on the Modes and Processes of Healing, as occurring Spontaneously in Disease, and on the Modes and the Processes of Dying, as resulting naturally from Disease. By ALEXANDER HARVEY, M.A., M.D. Edin.), Emeritus Prof., etc., etc. New York: D. Appleton & Co. 1879.

To summarize the author's views, his aim is not to glorify art—this very decidedly—but to yield to na-

ture her meed of credit in the cure of disease. He therefore, in his scepticism of the direct agency of art, speaks of *recoveries* rather than *cures*, and demonstrates, with a rare incisiveness of logic, that, although art, to use the memorable phrase of Cullen, "may obviate the tendency to death," nature alone is the restorer. It is more especially the bias of the uninformed and the credulous to overestimate art, regarding disease as an entity instead of a condition of the living organism. Physiology, the natural history of disease, and morbid anatomy have done much toward the revolution in medical opinion regarding the fanciful properties of many articles of the materia medica; so that now but few have really unchallenged merits. Because of the constant association with art of the *vis medicatrix*, it is really difficult to run the line with precision; but there can be no doubt that to the latter belongs the larger territory, and indeed the right of eminent domain.

In the lectures on the modes and processes of dying, there is more illustration than novelty, yet the omission of these topics would seriously detract from the value of the work. We may say that, as a contribution to the philosophy of medicine, this treatise, which may be profitably read during odd moments of leisure, has a happy method of statement and a refreshing freedom from dogmatism.

PHARMACOGRAPHIA: a History of the Principal Drugs of Vegetable Origin met with in Great Britain and British India. By FRIEDRICH A. FLÜCKIGER and DANIEL HANBURY. Second edition. London: Macmillan & Co. 1879.

THE remarkable sale enjoyed by the first edition of this work in Europe permitted but a limited number of copies to reach this country, and these, it will be remembered, were held at a premium above the original published price, and when the last copy was disposed of, the event was deemed of sufficient importance to merit a special mention in one of the English journals. The work has also appeared in other languages. This second edition, therefore, comes with an acquired prestige that will go far to make it a work that every physician will desire to add to his library.

The authors treat the various subjects in full detail, each being considered with respect to botanical origin, history, description, microscopic structure, chemical composition, uses, substitutes and adulteration—the information furnished being fuller than that contained in either of the dispensatories. The revision of the work has fallen to the lot of Dr. Flückiger (Mr. Hanbury being dead), and in it he has received the assistance of Dr. Charles Rice, of this city, whose pharmaceutical knowledge and philological acquirements have added much to the value and usefulness of the volume. This second edition, though containing increased matter, is offered at a lower price than was originally asked for the first.

A MANUAL OF THE PRACTICE OF SURGERY. By W. FAIRLIE CLARKE, M.A., M.B. (OXON.), and F.R.C.S., Assistant Surgeon to Charing Cross Hospital. From the last London Edition. Revised and Edited, with Additions, by an American Surgeon. New York: William Wood & Co., 27 Great Jones Street. 1879.

No one of these handy books is more opportune than the Practice of Surgery, now before us. It will be appreciated not only by the general practitioners, but the specialist, who wishes to be *en rapport* with the advances in those departments of medicine not strictly within the range of this work. Few of us, except those who practise general surgery, have the pecuniary means or time to wade through a bulky treatise on this topic. Many of us, and perhaps the best, are often obliged to accept opinions and methods, provided they have the stamp of a proper experience and the recommendation of a sound practitioner. These remarks apply to the case in hand. This little volume of 316 pages will be found an excellent manual for rapid reference. It is not complete, for it would be impossible to review even the outlines of the whole subject satisfactorily in so small a space; but it contains all that can fairly be expected of such a book. The errors are mostly in the field of surgical pathology, and are of little importance, or in the way of omissions; but the American editor has fairly atoned for this latter defect by inserting a very large number of notes, so that the whole subject is brought fairly up to date. The bracketed additions give us a short, clear, and succinct account of Bigelow's method in crushing a stone at a single sitting (litholapaxy); Buck's extension treatment for fractured thigh; Volkmann's method of amputating the rectum; Sayre's treatment of hip and spinal disease; Otis's plan in urethral strictures; Shrady's operation for tying the lingual; American studies on carcinoma, with their practical deductions; American researches on fractures, especially in those of the clavicle, and at the wrist, with new plans of treatment; Howe's rules for transfusion of blood; American methods in suspended animation; the use of Martin's elastic bandage; Heaton's radical cure of hernia by the subcutaneous injection of an irritating solution, and dozens of minor points that have suggested themselves to an ingenious and experienced surgeon.

COUNSEL TO PARENTS ON THE MORAL EDUCATION OF THEIR CHILDREN. By Dr. ELIZABETH BLACKWELL. Pp. 160. New York: Brentano, 39 Union Square.

THE writer, an esteemed practitioner of this city, takes high ground in favor of sexual morality, and, with Mr. Paget, combats the opinion that purity and perfect health are incompatible. She, however, advocates matrimony as the fulfilment of the social and physiological relations of the sexes. Still further, she maintains that this state tends to the elevation of both. The work, intended as it is for conscientious humanitarians, is a timely one, to be studied with profit, and reflects no little credit upon the writer. Its appeals to "the higher law" which should govern the race, if it expects to avoid degradation and eventual destruction, are made with justice and force.

A MINISTRY OF HEALTH AND OTHER ADDRESSES. By BENJ. WARD RICHARDSON, M.D., etc., etc. New York: D. Appleton & Co. 1879.

THIS publication comprises a number of agreeable addresses delivered at different times by the author, the first of which gives title to the work. To an eulogy on "William Harvey" succeeds "A Homily Clerico-Medical," in which the inter-relations of the two professions are portrayed in a very kindly manner. "Learning and Health" might more properly be designated "Health as Influenced by Methods of Learning." In this article the author indulges in sundry flings at medical specialists, and asks why clergymen do not also seek out special sins for reformation. The Procrustean mode of teaching with the avowed object of stimulating precocity, and with the usual result of early death, also shares the earnest invectives of our author. He points out that

the intellect of the world can be made up of only two classes of minds—the analytical and the synthetic—the one to sift out details, and the other to construct. Each should have its own intellectual work; and work, when congenial, becomes amusement. After a condemnation of the prize system as being fundamentally bad, we meet with the apt formulation of the whole argument, "Do not push on the strong, but help the feeble." "Vitality, Individual and National," is the fifth in the series of essays, and, as a statistical study, is comprehensive. To the Hebrew is awarded the palm of superior longevity, his triumph being due to persecution, which compelled him to husband his physical as well as material resources. Excessive athletic culture, worse than useless, is responsible for lost vitality, while purity, simplicity of life, mental culture, and absence of monotony tend certainly and surely to longevity. In the essay, "The World of Physic," our author deals with "the mutual relationships of the community of physic and the community at large." The warmth of the eulogy is somewhat toned down by a droll humor and a quaint bit of satire at the expense of a good Lama of Thibet. The article, though it contains many hygienic suggestions, is, on the whole, more hortatory than instructive. "Burial, Embalming, and Cremation" follow next in order. Burial in wicker coffins, on the third day after the demise, is advocated as establishing the fact of death and preventing injury to the living. Cremation, stripped of its fascinations, is held to be a failure in relation to natural economy, but more especially from a medico-legal standpoint. In brief, the formula "dust to dust" is both logically and rhetorically paraphrased. The tenor of the chapter on "The Registration of Disease" may be readily inferred. "Ether-drinking and Extra-alcoholic Intoxication" closes the collection. "Free as we are," says the writer, "when we are running in concert with nature, we are stopped whenever we try to go our own way."

To say that this series has interested us is no more than a truthful statement. The style, notwithstanding its diffuseness, is elegant and much in vogue on the platform. Intended, as the addresses were, for a miscellaneous audience, it would be unfair to criticise with severity; but the statement of facts is given with candor, and the conclusions, somehow or other, fall in line with the reader's convictions.

THE MULTUM IN PARVO REFERENCE AND DOSE BOOK. By C. HENRI LEONARD, M.A., M.D. Third edition. Revised and enlarged. Detroit, 1879.

A HANDY "vade mecum," which gives numerous anatomical, obstetrical, and therapeutical details. It is concise, epigrammatic, suggestive, and altogether an admirable remembrancer.

THE HEART AND ITS DISEASES, with their Treatment, including Gouty Heart. By G. MILNER FOTHERGILL, M.D. Second edition (entirely rewritten), with illustrations. Philadelphia: Lindsay & Blakiston. 1879. 8vo, pp. 476.

WHEN a physician, by the end of his tenth year in practice, has made himself a reputation as a prolific writer, it is natural to scrutinize pretty closely the fresh productions of his pen. Dr. Fothergill, besides his work on therapeutics, has written numerous monographs and papers for societies, is a regular correspondent of an American medical journal, and now rewrites entirely his work on diseases of the heart. Yet, Dr. Fothergill, although the matter that he writes is not always the best, has always written well, and he shows a thoroughness of scientific knowledge, a positiveness concerning therapeutical methods, and a warm enthusiasm in all subjects that he treats, which makes his writings popular, and, in a somewhat less degree, valuable.

The book before us is a great improvement in style over the first edition, and it is much more complete in matter. Dr. Fothergill always writes in an attractive way: one feels that an earnest man has hold of the pen, and is imparting some of the warmth of his own personality to the lines.

He is in marked contrast, in this respect, to our countryman, Dr. Austin Flint, who is clear, correct, and well-balanced, but as cold and unsympathetic as an annual report. Their respective works on diseases of the heart should hardly be compared. Dr. Fothergill's is distinctively that of a physiological therapeutist; Dr. Flint's that of a clinician. Dr. Flint's will serve quite as well for the ordinary practitioner; Dr. Fothergill's is vastly more interesting. As some little opprobrium hangs over physiological therapeutics, we may say that the treatment and practical suggestions in the two books do not differ very essentially.

The general method of arrangement in the present edition does not differ much from that of the previous one. The subject is introduced with a chapter on the evolution and physiological anatomy of the heart, which is rich in scientific interest, and contains the latest facts upon the subject in hand. The next two chapters cover the physical examination of the heart. The tracings given by the sphygmograph and their indications are written upon by Dr. Balthazar Foster.

The various diseases of the heart are then treated of in the usual order.

As regards therapeutics, we find the author's remarks here, as elsewhere, suggestive and in general judicious. Dr. Fothergill is, however, given too much to dogmatism and digitalis; his mind, indeed, is somewhat saturated with the latter potent and valuable drug. He recites the case of a woman who took it for forty years for disease of the heart, always feeling worse when she left it off. It strikes us that the alcohol in that digitalis must have been very good and the digitalis very bad. At any rate, it is wrong to relate a case which may leave the impression that digitalis continues to act as a heart-tonic for forty years.

In discussing acute endocarditis, the author insists strongly on the necessity of perfect rest and sedatives during and for some time after the disease, in order to lessen the likelihood of subsequent organic lesions. The point is an important one, and its forcible presentation here will do much service.

A very interesting chapter is that upon the gouty heart. The author takes the ground that in lithiasis there is a change in the arteriole walls, an increased arterial tension, a consequent cardiac hypertrophy, and eventually dilatation, mural and perhaps valvular changes—in fact, serious organic disease. These facts are to be borne in mind in the treatment of lithiasis and its renal complications.

Dr. Fothergill has not yet reached the rank of a classical writer. His style is still occasionally careless; he repeats himself, and some of his chapters, as that on the gouty heart, lack systematic arrangement. The book, however, is, on the whole, the best extant on the subject.

Reports of Societies.

IOWA STATE MEDICAL SOCIETY.

TWENTY-EIGHTH ANNUAL SESSION.

Held at Des Moines, Iowa.

DR. G. P. HANAWALT, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

THE Society convened in Odd-Fellows' Hall, in the city of Des Moines, January 27, and was called to order at 10 A.M. by the President, DR. G. P. HANAWALT, of Des Moines. REV. C. S. REYMAN opened the meeting with prayer, after which JUDGE G. G. WRIGHT, (late U. S. Senator from Iowa), delivered an interesting and eloquent address of welcome. All the officers were present, and the Committee on Credentials, reporting from time to time, showed an aggregate attendance of about two hundred.

THE LEGAL STATUS OF THE MEDICAL PROFESSION OF IOWA.

At 2 P.M. of the first day, the President delivered his annual address. His subject was, "The Legal Status of the Medical Profession in Iowa; its Rights, Duties, the Measure of Damage for Malpractice, and the Special Privileges and Prohibitions of that Class." He spoke particularly of the contrast between the provisions of the Code relating to the practice of law and medicine in the State; of the fact, that while several pages are devoted to the former, detailing the requirements, etc., of lawyers, only a few sections are devoted to the physician. In regard to the measure of damages, he said: "The jury is first to determine the condition in which proper treatment would have left the patient; how much more he would have earned in that condition than in that fixed by the actual treatment; and how much more it costs to keep him in the latter than in the former condition. It is also to consider the expectancy of life in both conditions. Theoretically, the jury should return in their verdict pecuniary damage in an amount sufficient to make his estate what it would have been if properly treated. Under this rule, that malpractice which results in *death* does not entitle the estate of the deceased to so great damages as if he had been left a bedridden, irritable paralytic, since, in the former instance, the estate loses but the earnings of the deceased and advanced funeral expenses, which must have come some time." He also considered this question:

"WHAT IS THE STANDARD OF PROFESSIONAL SKILL AT PRESENT REQUIRED OF AN IOWA PHYSICIAN BY LAW?"

"Against quacks and impostors, society has no protection in law-abiding Iowa. Our statutes afford no protection to patients nor encouragement to skilful physicians. The Code of Iowa requires the *lawyer* to be twenty-one years of age, a resident of the State, requisite learning, good moral character, etc. It prescribes for him several articles in matters of professional ethics, and an oath to maintain them; it also prescribes a civil liability for treble damages for any malfeasance resulting in loss, and a criminal liability for wilful wrong-doing, with the severe penalty of disbarment."

The doctor referred to two cases before the Supreme Court of Iowa, in which damages were claimed for alleged malpractice. In the absence of any statute defining the professional standard of a physician in Iowa, the majority of the court decided that one claiming to be a surgeon or physician was not required or expected to be "thoroughly educated" in his profession, but "the true measure of skill is that ordinarily exercised in the profession by the members thereof as a *body*." "Not that exercised by the *thoroughly educated*, nor yet that exercised by the *moderately educated*, nor merely of the *well* educated, but the *average* of the thorough, the well, and the *moderate*."

Respecting this the doctor said: "At the risk of being confronted some day in open court with my own opinion, I declare it to be that the standard of professional excellence prescribed by the opinion referred to above, is unworthy the profession in Iowa —a standard that any good physician would dislike to be represented by in conversation, however it might delight him if prosecuted for malpractice."

THE COMMITMENT OF THE INSANE.

A communication was received from the Scott County Medical Society relative to the "commitment of the insane," criticising the present law which requires the Board of Commissioners to consist of one lawyer, one doctor, and the clerk of the court, thus putting a majority of the board against the physician; also requiring that the criminal insane be not placed with the others, and recommending also some measures for the proper care of the *incurably* insane, who now, for want of better provision, were kept in our county poor-houses. The communication was referred to a special committee, who reported that the matters recommended were now being considered by the Legislature, and they recommended that the Society defer action until it was ascertained what was done by that body.

A NEW METHOD OF ARRESTING PUERPERAL ECLAMPSIA.

DR. G. M. STAPLES, of Dubuque, read a paper on "A New Method of Arresting Puerperal Eclampsia," of which the following is a brief abstract:

Dr. Staples claims to have promptly arrested puerperal convulsions with uninterrupted success for nine years past with hypodermic injections of veratrum and aconite, every twenty to thirty minutes, until the system was brought under their influence. Average dose, four to six drops of the former and two to three of the latter.

Norwood's tincture of veratrum and tincture of aconite root usually employed. Effects will be observed in fifteen minutes, and no ill results have been experienced in the punctures. He reports three cases in full from among those treated in this manner, in which the results were most gratifying.

In all three post-partum convulsions were present; patients were profoundly comatose; spasms were frequently recurring, and in one all other remedies had been exhausted in vain. He finds the two drugs combined more efficacious than the veratrum alone, while a smaller dose is required. He further claims that this treatment is equally efficient in spasms from other causes, and reports at length a remarkable case of a child suffering from protracted and incurable cerebral disease, where the convulsions were constantly arrested through several months after all the usual means had failed.

The paper elicited considerable discussion, participated in by Drs. Waples, Fitch, and Rawson of Corning; Tomson, Staples, and Archibald, in the main concurring with the treatment as recommended in the paper.

PARACENTESIS OF THE PERICARDIUM, WITH AUTOPSY.

Dr. Staples also made a report of a case of paracentesis of the pericardium, with autopsy, of which the following is a brief epitome:

Dr. Staples had, in June last, read a paper at the State Society, detailing a case of paracentesis of the pericardium, upon which he had successfully operated on the 7th of June, 1877. Patient was a child nine years old, and had suffered for several months, as alleged, from rheumatism. Child fell into his hands and he diagnosed hydropericardium, with cardiac hypertrophy and mitral insufficiency, and operated by aspiration, when patient was almost in articulo mortis, removing sixteen ounces of fluid. Great relief followed and patient recovered a fair degree of health, but never became quite well. There was slow but progressive hypertrophy, and patient died from effusion into brain, December 2, 1879, two years and six months after operation. The doctor thought his case took precedence of the one reported in the *Medical News and Library* for March, 1878, by Prof. Pepper, of the University of Pennsylvania, operated on September 11, 1877, by Prof. P., and claimed by him to be the second successful case in this country.

The present paper of Dr. S. gives results of the autopsy, which fully confirmed the diagnosis.

Pericardium universally adherent and heart enormously hypertrophied, weighing twenty ounces. Right ventricle and left auricle contained antemortem clots (latter greatly dilated with endocardium, roughened and gritty). Mitral insufficiency with cartilaginous degeneration of valve. No trace of puncture, and pleuræ healthy, except two or three adhesions on right side.

Dr. S. concludes that life might have been indefinitely prolonged had the operation been earlier performed.

OVARIOTOMY AND THE VALUE OF ANTISEPTICS IN THE AFTER-TREATMENT.

In the evening session, Dr. J. Williamson of Ottumwa read a paper on "Ovariotomy by Enucleation, with Remarks on the Value of Antiseptics in the After-treatment." The paper was listened to with interest. A brief synopsis of the case, with a letter from Dr. Bozeman, was published in the Medical Record of January 17th.

Immediately following, Dr. G. R. Skinner of Cedar Rapids read a paper on "A Case of Ovariotomy," which was singularly corroborative of Dr. Williamson's case, using successfully large doses of quinine and opium, which proved antiseptic, and depending almost entirely upon rectal alimentation and medication.

Dr. Angiar stoutly denied that material injected into the rectum could be absorbed, especially albumen. He said it was contrary to physiology. Several of the members gave instances that were at variance with physiology, as enunciated by Dr. Angiar.

Dr. Rawson spoke of a case which, as a sequel of diphtheria, had stricture of the œsophagus, and which for the last three weeks had been solely nourished by rectal alimentation. During the discussion Dr. Rawson gave a case of a girl, thirteen years of age, who had an ovarian tumor; she was tapped, and about six quarts of characteristic fluid was drawn off. The drainage through the trocar opening continued for some time, resulting in complete cure.

SOME OF THE NEW IDEAS OF THE NERVOUS SYSTEM.

Dr. W. D. Middleton of Davenport read an interesting paper on "Some of the New Ideas of the Nervous System," of which the following is a brief summary:

The author examined briefly the ideas of the "localization" of nerve-power, giving the latest observations in cell-structure, arterial supply and function, as established by physiological experiment and pathological changes. He also examined at length the recent ideas of Dr. Brown-Séquard in opposition to this new departure in nerve-science, and to what he calls the "old ideas." After many citations of cases brought forward by Dr. Brown-Séquard as inexplicable by usual brain theories, and their explanation in logical manner, from the observations of Flechsig on the cord, and other recent observations, the author commented on the sad picture of such a mind in its present iconoclastic attitude, expressed the opinion that progress lay only in a direction opposite to that of this man's present course, and predicted, in the not distant future, a complete organology of the contents of the cranium, by steady and faithful work.

ELEVATION OF TEMPERATURE AND TISSUE-CHANGE.

The following are the conclusions of a paper read by D. Scofield, M.D., of Washington:

(a.) That any elevation above the normal temperature of the body is attended by increased tissue-change. *(b.)* That the products of metamorphic change, when not properly and speedily eliminated, are toxic to the system, and cause not only an elevation of the temperature of the body, but also glandular derangement. *(c.)* That the autogenetic poison of pyrexia, and the specific poison of typhoid fever, are in many respects similar, having each a tendency to the same organs and glands, and are both alike amenable to the same general plan of treatment. *(d.)* That treatment, to prevent and control the typhoid condition, must necessarily embrace such means as are efficient to speedily reduce the temperature, and call into increased activity the secerment organs of the body.

Dr. J. L. Powers, of Rembeck, detailed two cases of crural phlebitis, one following parturition, the other in a man, forty-five years of age, of intemperate habits. Both cases had been treated on general principles indicated in such cases, but with little benefit for several days. Prompt and speedy relief was, however, obtained in each case by the application of a "tobacco salve."

TREATMENT OF DIPHTHERIA BY QUININE.

Dr. M. G. Sloan reported thirty-four cases of diphtheria treated successfully by quinine in large doses, alternated with sulpho-carbolate of sodium. He used locally zinci ferri chlor. and glycerine, applied gently to the affected parts, and in four cases of laryngeal complications he cured three by the use of inhalations of lime-water with the constitutional remedies named.

QUININE AS AN ANTI-CONGESTIVE REMEDY.

Dr. J. M. Knott, of Sioux City, read a paper on "Quinine as an Anti-congestive Remedy," of which the following is a brief résumé:

Quinia is a safe and certain equalizer of the circulation in all cases, whatever the type of disease, in which there is a tendency to local or general engorgements, and through this agency powerfully resists the formation of congestions in the early stages of disease, disperses them when already formed, and thus prevents an impending inflammation. When

he inflammation is already established, no remedy ‘ill, in the same degree, modify the attack and hasten he stage and process of resolution. The quinia will ›roduce the equalizing action unaided, and favor limination by skin and kidneys of the débris of sys-em, or poison, as the case may be. But the results ›re far better when it is aided in its work by a diu-etic and diaphoretic. (Profuse diaphoresis is de-irable.) This anti-congestive treatment is appro-›riate in all acute infections, and acute inflammatory liseases, and the inflammations due to injuries and ›urgical operations. When the patient is first seen never wait for preparatory treatment), administer ix or eight grains of quinia, combined with one rain of Dover's powder, and afterward two or three rains of quinia, with half a grain of Dover's pow-ler, every three hours. Alternate this powder with n average dose of potassa acetate. This course hould be pursued until the disease yields, when the nterval between the doses should be gradually ex-ended, and the diaphoretic omitted. These views are based upon an extensive use of the remedy in the nanner indicated, covering a period of eight years.

THE USE OF ANÆSTHETICS IN LABOR.

A paper was read by DR. H. L. GETZ, of Marshall-own, Iowa, on "Anæsthetics in Obstetrical Prac-ice."

Dr. Getz stated that the pain and suffering inci-lent to childbirth is, in what may be termed ordi-nary cases, often quite as severe and terrible to endure for woman as would be the amputation of a imb without the use of an anæsthetic.

Physicians, surgeons, or obstetricians, who do not elieve pain when it is in their power so to do, are leserving of being called barbarians in practice, no matter what the cause of pain is.

Having administered anæsthetics in over one hun-lred obstetrical cases, he gave the following as the conclusions he had arrived at:

Ether, though a safe anæsthetic, was not well calcu-ated for such, on account of its slowness of action; ts tendency to produce nausea and vomiting, aver-ion for food, and other minor objections. Nitrous oxide also had its objections, viz.: inconvenience of dministration, and a tendency to excite rather than o calm, unless completely under its influence.

As a rule, he preferred chloroform for the following easons:

A small quantity was sufficient; it was quick in its ction; not usually irritating to the air-passages; eldom produced nausea and vomiting; it relieved all gonizing pain; it retarded the progress of a case of abor, but in some cases it expedited it. It was neither injurious to mother nor child if carefully and roperly administered.

The instances in obstetrical, as in surgical practice, where anæsthetics are contraindicated, were organic lisease of heart or lungs. The new anæsthetic, nown as "bromide of ethyl," employed in a number f surgical cases in hospital practice by Dr. R. J. Levis, of Philadelphia, would probably be a good ubstitute for chloroform. There was claimed for it uicker anæsthesia and quicker recovery. He in-ended to try it in obstetrical practice.

Complete anæsthesia may be produced by chloro-orm without in the least degree influencing the con-ractions of the womb. A woman might be so com-letely under its influence as not to be able to exert muscle, and yet the contractions of the womb con-inue regular and strong, so that the head and body f the child were born unknown to the mother. An excessive anæsthesia should always be guarded against.

The expulsive muscular power of the abdominal muscles, which is lost by the use of chloroform, is more than compensated for by the greater readiness with which the perineum yields. Placing the hand over the region of the womb, and at each contraction carefully and gently simulating the contractions of the organ, you might assist in this artificial manner to a greater extent in the expulsion of the child than could the muscles possibly do were no anæsthetic employed. So long as the function of respiration and the involuntary contractions of the heart continued, the involuntary contractions of the womb would also continue. He believed that though a patient have sufficient chloroform administered to cause the heart to cease beating, the contractions of the womb would cease later.

The perineum lost its resistance in an equal ratio to the amount of chloroform administered.

There was no more danger of post-partum hemorrhage where anæsthetics are employed during labor, than where they are not. He had not seen one case of serious hemorrhage where chloroform had been used during labor; had seen it where it was not used. The pain incidental to confinement might, if not relieved by anæsthesia, produce sufficient shock to at least temporarily suspend the uterine contractions, and it was by avoiding this that chloroform might act as a preventive of post-partum hemorrhage. It did not affect the general health of the mother, it did not retard her convalescence. It was desirable in most, if not all, forms of disease, to keep the patient as calm and quiet as possible, to avoid all excitement; by the use of chloroform perfect composure of mind and body might be maintained, and it might be in this way that chloroform had a tendency to aid in recovery; and it might also have a tendency to avoid inflammatory troubles occurring after childbirth.

Chloroform would control puerperal convulsions in some instances, when all other remedies seemed to fail. It should be administered in all ordinary cases. In protracted obstetrical operations, ether would, as a rule, be safer. Anæsthetics should, as a usual matter, not be administered during the first stage of labor; the pain, though somewhat aggravating, is not usually so severe. If the patient, however, is nervous or irritable, enough to calm and quiet her may be given with good advantage.

Papers were also read by Drs. J. J. M. Angiar, of Fort Madison; Gustavus Hinrichs, of Iowa City; W. F. Peek, of Davenport; C. M. Hobby, of Iowa City; H. M. Dean, of Muscatine, and others.

The following officers were elected:

President, S. B. Chase, M.D., Osage; 1st Vice-President, T. J. Caldwell, M.D., Odell; 2d Vice-President, L. J. Alleman, M.D., Boone; Secretary, J. F. Kennedy, M.D., Des Moines; Assistant Secretary, M. H. Waples, M.D., Dubuque; Treasurer, G. R. Skinner, M.D., Cedar Rapids.

Dubuque was selected as the place for holding the next meeting of the Society, which will be on the last Wednesday in May, 1881.

PROVINCIAL BOARD OF HEALTH FOR ONTARIO.—Influential men are urging the formation of a health board for the Province of Ontario. It is likely that the movement will be a successful one. There are attempts also being made to collect health news from every part of the country, the data obtained to be published regularly from a central health office.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Jan. 6, 1880

DR. L. C. GRAY, VICE-PRESIDENT IN THE CHAIR.

THE Society was called to order and the minutes of the last stated meeting were read by the Secretary, Dr. Wm. J. Morton. The Council reported in favor of the election of Drs. Guy D. Daly of Flatbush, J. B. Matthews of Brooklyn, and L. Weber of New York, as active members, and the Society adopted the report.

THE HYSTERICAL ELEMENT IN ORTHOPÆDIC SURGERY.

The discussion on DR. SHAFFER'S paper on the above subject being next in order, he recapitulated the points which it contained as follows: he wished to direct attention to the muscular condition as an aid to differential diagnosis between true and simulated joint-disease, especially with reference to hip-joint disease and club-foot, the two conditions most liable to be simulated in consequence of the neuromimetic state. He also called attention to the invariable character of the muscular spasm in the true, while in the simulated joint-disease or in the neuromimetic state it is variable. In the simulated condition faradic contractility is normal, while in the true arthritic affection faradic reaction is diminished. In the false joint-disease atrophy of the muscles may occur from disease, while in the true affection there is genuine wasting of the muscles.

DR. HAMMOND remarked that he had seen cases corroborative of Dr. Shaffer's views, and referred to one in which there was notable atrophy of the muscles. The patient for three years was supposed to have actual knee-joint disease, and had worn a mechanical appliance. Competent surgeons pronounced it a case of true joint-disease. From certain general appearances he was led to diagnosticate hysteria, and seizing her by the hands, dragged her about the room—a method of treatment suggested by Meyer—and she at once walked perfectly well, and the cure was permanent.

DR. MARY PUTNAM-JACOBI asked if hysterical contraction yielded to the faradic current, and reported a case in which the patient had the left arm and right ankle tensely flexed—so much so that passive motion was difficult. Faradism was employed, and a cure effected.

DR. SHAFFER thought that Dr. Jacobi's case belonged to the emotional variety, and differed from the hysterical contracture described by Charcot.

DR. E. C. SEGUIN had been impressed by the fact that, in cases of joint and spine disease, the subjective element preponderates. The impression still remained in the mind of the profession that pain in the region of the spinal column indicates that there is real lesion of the spinal cord. On the contrary, there may be acute pain and no lesions whatever. A parallel existed between the neuro-mimetic spine and functional heart disease. In both, much pain was against real lesion, and, *per contra*, grave disease existed without the subjective evidence. He related two cases: one illustrating the hysterical element in both ankles, and the other in the left wrist. The first patient was a child who had extreme pain in both ankle-joints, without redness, swelling, or other signs of inflammation. The second patient was a precocious girl, who had intense pain with contracture affecting the left wrist. With the father's consent the girl was imprisoned in a dark room until the second day, when she was well.

DR. J. C. PETERS asked how great the difference was between the pain of the myelitis and that of spinal tenderness.

DR. SEGUIN replied that the difference was gigantic. In myelitis the spine could sometimes be pounded without producing pain; whereas, in spinal tenderness, extreme pain could be produced by slight pressure. He thought the diagnosis of spinal meningitis was altogether too common, aside from its existence in cerebro-spinal meningitis.

DR. PETERS remarked that he had been astounded to find how many considered tenderness of the spine as a symptom of real lesion.

DR. T. A. MCBRIDE referred to a case of a lady who had pain referable to the spine, with hemi-dysæsthesia and pain in the right inguinal region, with tender spots over the spinal column. She was visited by a surgeon acting for a railroad company, who diagnosticated railroad spine, and the lady recovered damages. The patient was of a nervous diathesis and given to self-abuse; her affection was hysterical, and she recovered.

He also mentioned a case of hysterical anuria, with right hemi-anæsthesia and left analgesia, and pain in the joints of the fingers.

DR. BRIDSALL remarked that Dr. Putnam-Jacobi's case recalled cases which he had seen under Charcot's care, in which the hysterical contracture was temporarily arrested by a series of electric sparks—dynamic electricity. In those cases ordinary faradism or galvanism had produced no effect.

DR. GRAY asked Dr. Shaffer if he had tested the muscular reaction by galvanism as well as by faradism.

DR. SHAFFER had contented himself with faradism, and had applied it in two hundred cases.

The Society then listened to the Report of the Committee on Asylum Abuses, after which it adjourned.

THE PHILADELPHIA ACADEMY OF NATURAL SCIENCES.

MICROSCOPICAL AND BIOLOGICAL SECTION.

Regular Monthly Meeting.

DISCUSSION CONCERNING THE CAUSE OF PLEURO-PNEUMONIA IN CATTLE.

DR. CHARLES TURNBULL read a paper on the peculiar round worm, or strongylus, infesting the air-passages of calves, which Dr. McCoart had been recently reported, in the Philadelphia daily papers, to have assigned as the cause of the supposed contagious disease of cattle known as pleuro-pneumonia.

Dr. Turnbull gave a very full and satisfactory account of the parasite, tracing its life-history through its various phases, some of which were supposed by eminent authorities to be passed in the intestine of the common earth-worm. From this intermediate host they were supposed to find their way to the grass and herbages eaten by the cattle, and thus be taken into their mouths, stomachs, and air-passages, causing a great amount of irritation and consequent expectoration when they have attained their adult state, and giving rise to the disease known as parasitic bronchitis, husk, or hoose. It most frequently affects animals pasturing on low, wet grounds, the relation between the parasite and abundance of earth-worms and their kindred varieties being evident.

DR. GADSDEN, being introduced, said he was not a

little surprised to read, in a report of the proceedings of the last meeting of the section, that these parasites were the cause of the disease known as pleuro-pneumonia. He thought it had been demonstrated beyond all possibility of doubt, by some of the most distinguished veterinarians, that the disease was specific and malignant, and was spread by the infection of healthy animals, through the medium of a specific virus derived from diseased ones. Many authorities were cited by the speaker, besides cases of his own in this country and England, to prove that such was the case. If this is not the case, then it is certainly to be considered a great waste of money by the State and general government to have appointed inspectors and established a system of quarantine over herds of cattle known to be affected, in order to prevent the spread of the disease. Not only does the anti-contagious doctrine reflect upon the wisdom of the policy of the State and general governments, but also upon a large and intelligent class of veterinarians, such as Professors Law and Gamgee. The fact of the existence of the disease in the United States interferes greatly with our export trade in live meat with England, whose House of Commons recently prohibited the importation of American cattle, which, on the authority of one of our government reports, were said to be diseased.

Dr. McCoart, being present, stated that he was very sorry, indeed, to have been misunderstood, and said that he did not mean to imply that the filariæ were the causes of pleuro-pneumonia, as he had been reported to have said. What he meant to convey was that parasitic bronchitis, or hoose, no doubt was often mistaken by amateurs for real pleuro-pneumonia. In reply to a question by Dr. Gadsden, Dr. McCoart replied that he did not consider that it had been proved that the disease was contagious.

Dr. Gadsden left some specimens of the diseased and healthy lungs of cattle for microscopic examination by the members. It was remarked that in pleuro-pneumonia but one lung was affected, the one on the other side remaining healthy. The diseased lung is filled up almost to solidity with lymph, and weighs as much as fifty pounds, while a healthy one weighs but three and a half pounds.

After further remarks by Drs. Seiler and Turnbull, the discussion was closed.

Correspondence.

SUCCESSFUL CASE OF TRANSFUSION.

To the Editor of The Medical Record.

Sir:—I went, during the month of August last, into Cheshire County, New Hampshire. While there, I was asked to see a patient of Dr. Richardson, in a consultation with Dr. Geo. B. Twitchell, of Keene, both of whom have been in successful practice for the last thirty-six years. On the day appointed for the consultation, Sunday, August 18, the attending physician, Dr. Samuel Richardson, was unable to appear on account of sickness, so we lost the benefit of any information that might have been gained from him. The patient herself gave the following history:

Mrs. B., widow, aged forty-five. Five weeks previously, while in an attic, she accidentally stepped from a beam (there was no floor) upon the lathing, and fell partly through into the room below, injuring her stomach, bowels, and back. Directly after this accident, she had severe cramps in stomach and bowels, followed by vomiting and constipation; the vomiting had continued every day, with the exception of five days, for five weeks. Dr. Richardson being absent, Dr. Twitchell took charge of the patient, and I saw no more of her until August 23, when I went on a visit to the house, and on account of her critical condition my stay was prolonged from two to ten days.

The gastro-intestinal catarrh became so severe that all nourishment was rejected; even a few drops of water would cause violent retching, and she was nourished with enemas of milk. After the 28th these were not retained, and her condition became exceedingly critical. At two o'clock of the morning of August 29th, I was called up and told she was dying. I found her without any pulse at the wrist, her respirations but five per minute, and her mind wandering; she was evidently in extremis. I gave her one drachm of carbonate of ammonia by injection, and though passed soon after, it had the effect of producing reanimation. About 9 A.M. of this day, I commenced to use injections of defibrinated blood, which were retained; still, at the same hour the succeeding morning I was again called, and was again obliged to administer the carbonate of ammonia by enema, with same effect as previous morning.

Saturday, Aug. 30.—As there was no very material improvement from the blood enemas, Dr. Twitchell and I canvassed the propriety of transfusion; we thought of sending to New York for instruments, but soon learned they would not arrive before Monday night, when our patient might be beyond our ministrations.

Dr. Twitchell had an old-fashioned canula, used by his deceased uncle, but no trocar to fit; having this simple instrument, and an ordinary pocket case, we determined to improvise the rest. We selected the fountain syringe as the most compatible apparatus, and appointed Sunday, at 11 A.M., for the operation. At that time, Dr. Twitchell arrived, and after some time spent in argument, a son of the patient consented to have the required amount of blood taken from his arm, whereupon Dr. Twitchell opened his median cephalic vein, from which we drew from six to eight ounces of blood, which was kept in motion by a tablespoon during the venesection, and afterward was strained or filtered through an ordinary pocket-handkerchief to remove any possible coagula; the quart-bowl was then placed in a pan of warm water; the fountain syringe was filled with the water, for the double purpose of cleansing and warming. With this simple apparatus we proceeded at once to the patient's room, where our efforts, for a time, were very disheartening, from the fact that fatal syncope threatened to supervene the moment the operation was commenced, and it was rendered more difficult from the emptiness of the veins. Instead of using trocar and canula, as we might have done with Collin's apparatus, a dissection was necessary, after which the vein was lifted up, opened, and the canula inserted. This had a shoulder about half an inch from the end, to prevent the blood from returning from the wound during the transfusion. To the free extremity of the canula we attached the hose of the fountain syringe; after filling both with the blood kept at the right temperature, the rubber bag was then elevated about four feet above the patient, who remarked to the assistant in a whisper (she could not speak aloud), "I feel that blood." From some defects in the foot of the canula a portion of the blood was lost upon the bed-clothing, and we concluded to supple-

ment it by more from the vein, as we removed the dressing and drew six ounces more. This we were able to inject entire.

Directly after the operation the patient's lips showed an increase of redness, the cheeks were flushed, and the pulse was greatly improved. Soon after this she complained of "tightness of the chest," and during the next twelve hours had some elevation of temperature, but no chill; slept some that night, and next morning commenced to take nourishment; during the next twenty-four hours she was able to retain one table-spoonful of fresh milk every three hours, the first nourishment by stomach for six days and nights. The milk diet, with a slight increase in quantity, was kept up until Tuesday, at 2 P.M., at which time I returned to New York and am indebted to Dr. Twitchell for further particulars, which I can give in no better way than quoting his letter of Sept. 17th.

"KELSO, Sept. 17, 1879.

"MY DEAR DOCTOR:—I presume you have heard from our patient. She continued to improve after you left. The only drawback was an ophthous inflammation of her mouth and throat, but this was almost entirely gone when I saw her last, and I saw no reason why she would not come out all right. I saw her on Thursday last, Sept. 11th, and since then have heard nothing unfavorable, so I do not doubt that she is doing well, and our operation of transfusion was a success. I shall be the more ready to resort to it again. . . . . .

Yours truly,
GEO. B. TWITCHELL.

I would here add that I received a letter from this patient a few days ago, reporting her complete convalescence.

Yours truly,
S. A. MASON, M.D.

75 EAST SIXTY-FIRST STREET, N. Y.

THE CURE OF CATARACT BY ELECTRICITY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Under the above heading the following remarks appeared in the last issue of the MEDICAL RECORD: "It will, no doubt, delight members of the profession, and oculists in particular, to be informed, on the authority of the *Churchman* (which claims positive knowledge), that Dr. Neftel cures cataracts . . . . . by certain electrical manœuvres."

The subject is certainly of high interest to the profession in general, and to oculists in particular, and they will probably now read my article in Virchow's Archives.

I may perhaps add a few words with reference to the history of the subject. My first researches on the optic apparatus, made about twelve years ago, were published in 1871, but scarcely attracted any attention, and were even ignorantly ridiculed by a reviewer in the *Richmond and Louisville Medical Journal*. I continued, however, my investigations, and published the physiological and pathological part in the *Archiv für Psychiatrie und Nervenkrankheiten*, which was favorably commented upon by Professor Rosenthal, of Vienna, the author of the excellent works on nervous diseases.

With the publication of my article on the electrical treatment of cataract in Virchow's Archives, I hope there will be no excuse for ignoring it.

Yours truly,
WM. B. NEFTEL.

NEW YORK, February 14, 1880.

[The answer is quite satisfactory, as far as it goes, and will doubtless prove of interest to oculists. In the meantime, we take the opportunity of thanking the *Churchman* for so kindly drawing the attention of the profession to the subject.—ED.]

A HERNIAL SYRINGE AND A QUESTION OF PRIORITY OF INVENTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In the MEDICAL RECORD of February 7th I notice a communication from the pen of Wm. B. De Garmo, M.D., on the Heatonian method of treating hernia, with a cut of an instrument that he has had made for this operation. Considerable time has now elapsed since I had made in this city, by Mr Gemrig, an instrument for the treatment of hernia according to the Heatonian method—an instrument similar in every respect as to the trocar arrangement for concealing the knife or point of needle after puncturing the skin and fascia, and entering the inguinal canal at the abdominal ring; that is, a movable hollow stem or probe, attached to the syringe by a socket-joint; an orifice at the terminal end of the hollow probe on the side, one-twentieth of an inch from the end, for the fluid to be injected on to the rings. Fitting over this tube or hollow probe a sheath one-third of an inch shorter than the hollow probe, with a cutting edge at its distal end similar to an ovarian trocar or the distal end of a hypodermic needle, with a bayonet-joint for locking the sheath to the probe. When set for use, the cutting edge projects over the end of the hollow probe one-fourth of an inch. After perforating the tissues and entering the external abdominal ring, the sheath being held firmly, the hollow probe connected with the syringe is turned so as to unlock the bayonet-joint, and then by gently pushing the syringe the hollow probe is made to enter the inguinal canal; at the same time, the needle or knife is retracted along the side of the probe, which it fits closely, completely protecting the knife, so that no injury can be done to the parts.

This instrument that Dr. De Garmo represents in the cut is the counterpart of the one that I have used for the radical cure of hernia, according to the Heaton method, in the Philadelphia Hospital, in the presence of several members of the surgical staff and resident surgeons, and in a public clinic where several hundred students were present to see the operation. It is now six weeks since three cases were operated on at the Philadelphia hospital with this instrument. I can assure you that I was very much surprised to see my instrument described in your journal. Is it possible that two persons at distant points, considering the same subject at the same time, should arrive at the same conclusions and have made instruments identical, even as to the joints and ring on the sheath for moving that sheath, as well as all other details.

Very truly yours,
WM. S. JANNEY, M.D.,
Surgeon to Philadelphia Hospital.

1535 N. BROAD STREET, PHILADELPHIA, Feb. 9th.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 8 to February 14, 1880.

TAYLOR, M K., Captain and Asst. Surgeon. To repair to Washington, D. C., and settle his accounts with the Treasury Department. On completion of this duty, to rejoin his proper station. S. O. 30, A. G. O., Feb. 7, 1880.

MCELDERRY, H., Captain and Asst. Surgeon. Relieved from duty in Department of the East, to proceed on or before March 1, 1880, to Fort Omaha, Neb., and report in person to Commanding General, Department of the Platte, for assignment to duty. S. O. 29, A. G. O., Feb. 6, 1880.

HOFF, J. V. R., Captain and Asst. Surgeon. To report in person to Commanding General, Department of the East, for assignment to duty at Fortress Monroe, Va. S. O. 29, C. S., A. G. O.

HALL, WM. R., 1st Lieut. and Asst. Surgeon. The leave of absence granted him December 5, 1879, from Headquarters, Department of the Columbia, is extended three months. S. O. 32, A. G. O., Feb. 10, 1880.

APPEL, D. M., 1st Lieut. and Asst. Surgeon. So much of the order of December 29, 1879, as relieved him from duty in Department of the Missouri, is revoked. He will report in person to Commanding General, Department of the Missouri, for assignment to duty. S. O. 32, C. S., A. G. O.

CUNINGHAM, THOS. A., 1st Lieut. and Asst. Surgeon. His leave of absence granted him January 26, 1880, from Headquarters, Department of Dakota, extended one month. S. O. 19, Mil. Div. of the Missouri, Feb. 9, 1880.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending February 14, 1880.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

OLEOMARGARINE.—A bill has been introduced to prevent the sale of oleomargarine for genuine butter, by obliging sellers to stamp the firkins with the word "oleomargarine."

BURIAL PERMITS.—A bill has been introduced making burial permits issued by the Boards of Health of New York and Brooklyn good in any part of the State.

FOURTEENTH ANNUAL REPORT OF THE CONNECTICUT HOSPITAL FOR THE INSANE, FOR 1879.—The Superintendent, Dr. Strew, reports that 644 patients have been treated in the asylum during the year. Of these, 45 were discharged cured, being 25 per cent. of those admitted during the year. The mortality was 19, or about 11 per cent. on the number admitted. The number in the hospital at the close of the year was 510. A history of the growth of lunatic asylums is given.

PROFESSOR BOLL, of Rome, has recently died. He was the first to study the subject of the visual purple.

SIXTH DECENNIAL PHARMACOPŒIA CONVENTION.—By virtue of authority devolved upon me as the last surviving officer of the Pharmacopœia Convention of 1870, I again call the attention of "the several incorporated State medical societies, the incorporated medical colleges, the incorporated colleges of physicians and surgeons, and the incorporated colleges of pharmacy throughout the United States," to the importance of appointing delegates to the Sixth Decennial Pharmacopœia Convention, and of sending the names and residences of the same to me for publication. The Convention meets on the first Wednesday in May, 1880, and I am required "to publish the names and residences of the delegates, for the information of the medical public, previous to its meeting."

I have received so far, the names and residences of the following delegates:

From the Massachusetts College of Pharmacy, Boston: Prof. G. F. H. Markoe, Ph.G.; Samuel A. D. Sheppard, Ph.G.; Thomas Doliber, Ph.G. From the Philadelphia College of Pharmacy: Prof. John M. Maisch, Alfred B. Taylor, Prof. Joseph P. Remington. From the Louisville College of Pharmacy: Prof. Emil Scheffer, Prof. C. Lewis Diehl, E. Vincent Davis. From the Maryland College of Pharmacy, Baltimore, Md.: *Delegates*—William S. Thompson, Louis Dohme, Joseph Roberts. *Alternates*—Charles Caspari, Jr., Dr. John F. Moore, Dr. Robert Lautenbach. From the Medical Society of the District of Columbia: Prof. D. W. Prentiss, M.D.; Professor Thomas Antisell, M.D.; Emeritus Prof. James E. Morgan, M.D. From the National Medical College of Columbia University, Washington, D. C.: Prof. W. W. Johnston, M.D.; Prof. D. W. Prentiss, M.D. From the Medical Department of the University of Georgetown, D. C.: Prof. W. H. Ross, M.D.; Prof. C. H. A. Kleinschmidt, M.D., and Dr. S. C. Busey. From the National College of Pharmacy, Washington, D. C.: Mr. W. S. Thompson, Prof. Oscar Oldberg, Mr. R. B. Ferguson.

(Signed,) JAMES E. MORGAN, M.D.,

Washington, D. C., January 20, 1880.

PROFESSIONAL ADVERTISEMENTS.—The names, addresses, specialties, and places of graduation of a number of physicians of Grand Rapids, Mich., appear as advertisements in the *Grand Rapids Daily Leader*. The paper endorses them as representing the reliable medical talent in that place.

OFFICE-THIEVES.—The office-thief is around again. It is well to instruct servants to keep a lookout upon strangers who come at odd hours and insist upon waiting for the doctor.

ATROPIA IN POST-PARTUM HEMORRHAGE.—Dr. George S. Ellis, of Boonville, Miss., writes to us that he has recently used atropia in post-partum hemorrhage with the best results. He was summoned to a case one evening, and found that the child had been delivered half an hour previously. The woman was pale, pulseless, and her uterus distended with blood.

He at once gave gr. $\frac{1}{100}$ sulphate of atropia hypodermically. He then emptied the uterus, kneaded the abdomen, and gave a drachm each of the fl. ext. of ergot and tinct. digitalis. Cessation of hemorrhage and improvement in circulation began at once. Dr. E. attributes all the good effects to the atropia, which, he thinks, acted by stimulating the respiratory and cardiac centres, by stimulating the muscular fibres of the uterus and contracting the arterial walls. Dr. E.'s experience leads him to agree with Dr. Brown-Séquard that atropia acts like ergot.

Reducing the Educational Standard.—The Medical School of the University of London has heretofore had its examinations so rigid that not more than five per cent. of the candidates for diplomas were successful. An examination in mental philosophy was one of the requisites for a degree. It is now proposed to lower this high standard a little, so as to give more students the educational advantage of the school.

Cure of Tetanus.—A case of tetanus cured by chloral is reported by Dr. J. H. White. From $\frac{3}{i}$ss. to $\frac{3}{iv}$. were given daily p. r. n., for three weeks. Another case is reported by Dr. Geo. Ross, cured by chloral and bromide of potassium, with the adjuncts of chloroform and morphine. During the three weeks of treatment, potas. brom. $\frac{3}{ij}$, chloral hydrat. $\frac{3}{v}$., morphia sulph. gr. xxss., and chloroform f. $\frac{3}{ij}$., were used.—*Va. Med. Monthly.*

The Eclectic Medical Institute of Chicago.—The diplomas of this institute failed to be recognized by the Illinois State Board of Health, because they were granted upon practically a one year's course. The institute having recently promised to do better and demand a three years' course of its pupils, the Board consented, at its last meeting, to grant recognition to its graduates.—*Chicago Med. Jour. and Examiner.*

Iodized Phenol.—Battey's formula for iodized phenol, iodine cryst. $\frac{3}{ss}$., acid. carb. $\frac{3}{i}$., is highly recommended by Dr. W. J. H. Bellamy in other than uterine affections. He has found it very useful in certain skin diseases, particularly those attended with itching. In eczema marginatum it works very promptly. It is to be diluted generally with equal parts of glycerine, and applied twice a day.—*North Carolina Med. Jour.*

Medicated Spray in the Treatment of Diseases of the Conjunctiva.—Dr. J. A. Andrews recommends the use of the atomizer in many conjunctival affections. Although not especially hastening cure, it is claimed that much less discomfort and annoyance is given to the patient. The Davidson atomizer is preferable, because it can be worked with one hand. Two per cent. solutions of sulphate of copper, alum, or potas. chlorat., may be used. In corneal inflammation, care must be taken to avoid spraying the cornea.—*Archives of Medicine.*

Georges Herbelin, interne of the Hospital Sainte-Eugénie, Paris, died on January 3d, of diphtheria contracted in his service in the hospital. On the evening before his death he was decorated with the Cross of the Legion of Honor.

Provident Dispensaries.—The Medical Institute of Liverpool refuses to give its countenance to provident dispensaries, because they are business institutions and liable to abuses.

The Dentaphone.—This is an instrument similar in principle to the Graydon audiphone, previously described in these columns. It is made in Cincinnati. According to Dr Turnbull, in the *Archives of Otology*, it is quite as efficient as the ordinary audiphone.

Typhoid Fever is not always the result of contagion, nor the product of filth, according to a number of authorities who have had experience in new countries. Mr. J. R. Exley writes to the *Lancet* that, after sixteen years' experience in New Zealand, Fiji, Western and Southern Australia, New South Wales, and Zululand, he comes to the following conclusions: 1. That a fever exactly like typhoid occurs in all those countries. 2. That in no case has he ever been able to trace the origin of this fever to contagion, although he had made special efforts to do so. 3. That in a few cases the disease seems to have arisen from the fouling of drinking-water by excremental matter. In the majority of cases the disease seems to have occurred among Europeans first inhabiting a virgin soil. This fever is sometimes called "hybrid fever" by army surgeons, not because it differs from typhoid in symptoms, but because they cannot account for it on the etiological theories of Budd, Watson, and Murchison. It is probably what we on this side of the Atlantic call typho-malarial fever.

The University of Michigan.—The medical department of this university announces a three years' course, of nine months each year, beginning October, 1880. Preliminary examination is also to be required.

San Francisco City and County Hospital.—This hospital is conducted in a way that strikes Easterners as somewhat novel. The building is a large one, and holds four hundred patients. The visiting physicians and surgeons are appointed exclusively from the faculties of the two medical schools of the city. They are paid $100 a month, and use the wards for clinical instruction to their pupils. The house-staff is not allowed to treat cases, it is said, but must in almost all cases wait for the visiting physician or surgeon. The hospital is said to be badly constructed as regards ventilation and drainage.—*Western Lancet.*

Tight Lacing the Fashion.—Dr. Dyce Duckworth, in *The Practitioner*, laments the fact that small waists are again to be in vogue, and that tight lacing is in consequence increasing. He finds the practice of wearing too small stays quite prevalent, even in the class of women that enters hospitals.

Many cases of dyspepsia in women yield quickly to the use of larger and better fitting stays. Chronic vomiting in young girls is often caused solely by tight lacing. Palpitation and dyspnœa are found to be due sometimes to the same cause. Proper exercise and free respiratory movements are also prevented. Stays of proper form, however, will serve an excellent purpose, affording warmth and support to the wearer. But the abuse of this article is always liable to become very great in obedience to the dictates of fashion.

The American Monthly Microscopical Journal is a new journal, edited and published by Romyn Hitchcock, in New York. It is intended to be a repository of short, original articles, which shall be popular and useful to microscopical students. The first number contains several such articles, and we should judge it to be an interesting one to persons especially devoted to the microscope.

Successful Removal of the Uterus.—In a case of ovariotomy, operated on by Dr. T. G. Thomas at

the Woman's Hospital a few weeks ago, the uterus was entirely removed with the tumor. The tumor was a cystic one, and firmly embedded in the uterus. A ligation was placed around the neck, and amputation performed just above this. No other special measures were adopted. The tumor was a very large one, weighing about forty pounds. This is, we believe, the first successful case of removal of the whole uterus that has occurred in New York.]

Japanese Medicine and Surgery.—The Ainos, a tribe in the north of Japan, manufacture one of the most popular of Japanese medicines. They first catch female bears, then take the heart, lungs, kidneys, and liver, and make a sort of sausage-meat by chopping them all up together, gall-bladder included, and drying them in cakes. This is purchased as medicine all over the empire, and is taken by simply cutting off slices and eating them. The taste is very bitter. It is used in diseases of the alimentary canal.

The aboriginal Japanese surgery is very rude. They use the moxa and the lancet. Syphilis was known and described three centuries ago. Mercury has been used in its treatment.

On the whole, the Japanese do not seem likely to furnish any new ideas to medical or surgical science. —*Chic. Med. Journal and Exam.*

Chloroform Narcosis and Nitrite of Amyl.—Dr. John Burke of this city writes: "On reading a recent number of the Medical Record, I saw an account of the death of a boy in the office of Dr. Vanderveer, at Somerville, N. J., from chloroform. Such a sudden death almost occurred to me last summer, which I will relate. If it will help my professional brethren, I will feel very much gratified. Besides, on that occasion 'I know how it was myself.' Last summer I had to perform a small operation on the vagina; the patient being very sensitive, I proposed giving chloroform. My assistant, who had been an interne at Bellevue, came to the house without the nitrite of amyl, which, since the discovery of its usefulness, I invariably have with me when chloroform is about to be inhaled. He was just going to give the anæsthetic, but something struck me that I had better send for it. I told the doctor my fears, and said that he must find some nit. amyl. The doctor, after half an hour's delay, returned with it. The doctor gave the chloroform on a pocket-handkerchief. Before this she had taken one and a half ounce of rye whiskey, which I invariably give before employing chloroform. I had introduced the speculum into the vagina, when the doctor nudged me. On looking at her she was apparently dead, pulse gone, heart ceased, face blanched, no breathing, mouth shut. My gracious! I thought that I would choke.

"In a moment I had perhaps twelve drops of the nitrate applied to the mouth on a towel, tongue dragged out by tenaculum. For a moment no response, then a slight purple streak through the cheeks, then a slight reddish tinge, then a feeble pulse, then the cheeks brilliantly suffused, then breathing returned. In a few moments more she had sense enough to put out her tongue when spoken to. I am certain that all this occurred in less than a minute. I breathed freer. I have given chloroform hundreds of times in the last thirty years. I saw the first patient, who died of it in this State of New York, cease to breathe on the operating-table at the old New York Hospital in the winter session, 1847–1848. He was a big, burly man—I think an United States Marine. Dr. Alfred C. Post was about to operate for piles, when the man ceased to breathe. They ran for the galvanic battery; there was evidently great commotion in the amphitheatre, but before anything could be done the man was dead. The post-mortem showed that the man was sound in every way. No cause was assigned for his death, unless spasm of the heart. The heart was healthy, but it was apparently small and contracted. My patient had not inhaled one drachm. The doctor was very careful. I was inclined heretofore to think that sufficient care was not employed in fatal cases, but I have gotten over that idea now. With utmost care, chloroform will sometimes cause sudden death, and we ought to be prepared for the emergency. Sulphuric ether is much safer. This woman was apparently dead from paralysis of the heart, and were it not for the nitrite of amyl would be surely dead. Think of it—pulse gone, heart stopped, breathing ceased, mouth closed—all this in a second. It is said that if too much nitrite be inhaled, bad consequences are apt to follow. Four drops is about the dose, but I think she must have had at least twelve drops on the towel."

The Annual Report of the Brooklyn Eye and Ear Hospital shows that during the year 1879 the total number of new patients treated was 4,123; of these 2,409 were eye patients; 1,067 ear patients; and the rest skin, throat, and nervous cases. The total number of visits during the year was 20,565. The number of surgical operations on the eye was 484; on the ear, 55; on the skin and throat, 51. The number of in-patients during the year was 69; cost of board, 25 cents per day.

Fatal General Peritonitis from Foreign Body in the Appendix Vermiformis.—Drs. T. F. Leech and E. W. Keegan send us a history, read before the Montgomery County (Ind.) Medical Society, Dec. 3d, of the above case.

The patient, a previously healthy girl, eight years old, was found, August 24th, suffering from constipation, great pain, and frequent vomiting; temperature, 102°; pulse, 115. The abdomen was very sensitive, and in the hypogastric region there was a distinct non-fluctuating tumor. On examination by rectum this tumor was felt, filling up nearly all the pelvis; it felt like cellulitis. There was no tumor in the right iliac fossa, so that perityphlitis was excluded. Drs. Keegan and Leech both reserved the diagnosis. The treatment consisted of mild purgatives, injections, anodynes, soothing local applications, and supporting measures. The patient died at the end of a week.

The autopsy revealed the following condition: deposited in the appendix, about one inch from the cæcum, were two concretions, each about the size and shape of an ordinary capsule. They each contained from four to ten grape-seeds, upon which were deposited dried fæces and secretions of the bowels. The hardened masses had gradually caused ulceration and perforation of the appendix, when some of the secretions probably escaped into the peritoneal sac. No lumps, however, were found outside of the appendix, nor was it dilated at all. That it was perforated was shown by the fact that a very little pressure caused the two concretions to escape through an opening in the side of the appendix. The peritonitis thus excited seemed to have first extended to the lower end of the epiploön, ileum, and the abdominal wall surrounding the iliac fossa, passing thence down into the brim of the pelvis, as all this part was gangrenous. The walls of the ileum were inflamed and paralyzed, the bowel being in a state of extreme distention; two loops of this extended down into the

pelvis, and formed the tumor felt in that locality. Throughout this portion of the body the adhesions were very great, the bowels being adherent to the walls of the abdomen and to each other. The peritonitis had become general before the death of the patient, as all the serous surfaces were covered with plastic lymph, and the abdominal cavity seemed to be full of a sero-purulent fluid.

University Medical College, N. Y., Commencement.—The annual commencement exercises of the Medical Department of the University of the City of New York took place at the Academy of Music on the evening of Tuesday, Feb. 17th. The Chancellor, Rev. Howard Crosby, D.D., read a portion of the Gospel of St. Matthew, after which the Degree of Doctor of Medicine was conferred on two hundred graduates.

Honorable mention was made of the following members of the class for proficiency and superior excellence as shown in their examinations: L. H. Hunt, F. Oakes, W. T. Van Dyck, D. Haig, S. M. Mousally, H. A. Pardee, G. M. Hammond, G. A. Thompson, J. K. Crook, W. H. Crocker. Honorable mention was also made of the theses presented by the following gentlemen: S. M. Mousally, on "The Diagnostic Value of Pain;" H. A. Pardee, on "Ethylic Alcohol;" M. B. Sullivan, on "Chronic Cystitis;" J. D. Kelly, on "Strangulated Inguinal Hernia;" G. F. Brooks, "Aneurisms;" E. A. Ayers, on "Massage."

The Mott prize medals for the best two anatomical preparations were awarded as follows: gold medal to T. H. Burch, silver medal to S. C. Blaisdell, and the Mott bronze medal for the best book of recorded cases of the surgical clinics to W. E. Dold. The Faculty having offered a prize of $100 to the candidate who should pass the best examination for his degree, and the examinations having shown that three gentlemen possessed equal merit, decided to award $100 to each of them, viz.: Leigh Harrison Hunt, B.S.; Frederick Oakes, A.B.; William Thomson Van Dyck.

Prizes for the best examination in the following branches were awarded as follows: pathology and practice of medicine, to W. H. Snow; materia medica and therapeutics, to David Haig; physiology, to Leigh H. Hunt; obstetrics, to L. R. Quackenbush; chemistry, to Leigh H. Hunt; surgery, to L. N. Hilleary; ophthalmology and otology, to S. Outwater.

A valedictory address was delivered by Robert Chalmers Davis, A.B., of the graduating class. The address to the graduates was made by the Hon. Charles C. Jones, of Georgia.

Grafulla's band officiated on the occasion. The Academy was crowded with a fashionable and appreciative audience, and the floral decorations were profuse and tasteful. The embellishments of the stage consisted of tastefully arranged palms, ferns, and spotted plants, together with a large shield of variegated flowers, bearing the legend, "Class of '80," and the symbolic *caduceus*.

Dr. John Neill, one of the authors of *Neill & Smith's Compendium*, died Feb. 11, of Bright's disease, at his home in Philadelphia, at the age of 70 years.

Boracic Acid not a New Remedy in Eye Diseases, and Optico-Ciliary Neurotomy not a New Operation.—Dr. E. Gruening, Surgeon to the New York Eye and Ear Infirmary, has written us a note stating that Dr. Theobald's claim for originality in the use of boracic acid in eye diseases is unfounded. In fact that article has been employed by ophthalmologists for many years, and Alfred Graefe, Weeker, Just, Becker and others, have written about it. The value of boracic acid as an antiseptic was brought out in a discussion at Heidelberg and Amsterdam during the past year.

He also states that the operation claimed by Dr. Chisholm is not original, in proof of which he refers to the labors of Graefe, Meyer, Landesberg, Boucheron, Schöler, Vignaux, Hirschberg, Mauthner, and a number of American ophthalmologists.

Hospital Saturday and Sunday Collection.—The total amount collected on the days set apart as hospital Saturday and Sunday was at first estimated to be about $75,000. It appears, however, that this was an over-calculation. The amount, as reported recently by the committee, is $25,000.

Nitrous Oxide Gas is used by Dr. Skene to produce anæsthesia in insane women undergoing uterine examination. The gas often has a beneficial after effect. Dr. S. finds that insanity diminishes functional uterine disorders, and often suppresses menstruation.—*Archives of Med.*

Donations to Hospitals.—By the will of the late ex-Secretary Borie, the hospitals of Philadelphia receive a large amount of money. Five thousand dollars apiece is left to three hospitals: Pennsylvania Hospital, Hospital of the Protestant Episcopal Church, and St. Joseph's Hospital. One thousand dollars apiece is given to the Children's Hospital, Will's Hospital for the Blind and Lame, and the German Hospital.

Books Received.

How to Work the Microscope. By Lionel S. Beale, F.R.S. Fifth Edition. London: Harrison, Pall Mall. Philadelphia: Lindsay & Blakiston. 1880.

Transactions of the N. H. Medical Society, 1879.

Answers to Correspondents.

W. F. A., *Salt Lake City, Utah.*—Are eczema and kindred diseases of the skin more common in the hot, moist, and equatorial regions near the ocean, or in the dry, cool, and mountainous regions of the interior of North America?

[There are not statistics nor facts enough to warrant the expression of any opinion.—Ed.]

W. F. A.—Is "*rigor mortis*" a common occurrence in sudden death from blows about the head, examination showing no lesion of cerebral substance? Ditto, in sudden death from apoplexy (cerebral hemorrhage)?

[It is stated by Woodman & Tidy (Forensic Medicine, etc., 1877), "that animals dying with an increase of their natural or normal temperature speedily become very strongly rigid. This happens in smallpox, acute rheumatism, tetanus, meningitis, abdominal diseases, pyæmia, and the like." "Increased heat, especially about 12° (Fahr.) above the normal temperature of an animal . . . . if long-continued, tends to bring about a permanent loss of irritability, or rigor mortis, from coagulation of the myosin." (See Niderkorn: De la rigidité, etc.; Onimus: Le Mouvement Médical, Feb., 1873; Nysten: Recherches de Phys. et de Chimie, 1811; Michael Foster: in Burdon-Sanderson's Handbook for the Physiological Laboratory; Dowler: Experimental Researches, etc., New York, 1846). A sudden, sharp blow, has been known to produce the same effect" (W. & T.).

To the writer it is suggested that an answer to the first question may be greatly facilitated by an experiment on any one of the lower animals.—Ed.]

Original Lectures.

AORTIC ANEURISM.

A Clinical Lecture delivered at the Pennsylvania Hospital, Philadelphia.

By J. M. DA COSTA, M.D.,

Professor of Clinical and Didactic Medicine in Jefferson Medical College.

(Special Report.)

H. D——, æt. 48, born in Scotland; a man with a good family history. The most careful examination has failed to elicit the evidence of any specific disease. The patient has been generally in good health himself except for an occasional cough. Two years before his admission to the surgical wards of the hospital, which was in the latter part of 1878, he fell from a step-ladder and received a severe contusion on his chest, but the effects of this injury soon passed away. His occupation, which has been that of a carpenter, has compelled him to work hard and to lift heavy weights. He has never experienced a sensation of anything giving way in his chest, and has never received any injury to his bones.

When first admitted to the surgical wards he complained of attacks of severe pain in his left shoulder, which sometimes extended into his chest. It was for this pain that he was admitted into the wards. Before he came into the hospital this pain was regarded as of rheumatic origin, and he was treated for rheumatism, but got no better. While trying to inform himself of the exact position of this pain, so as to be able to describe it the better, his attention was attracted to a throbbing sensation in his left chest, which was most marked when he was in the recumbent position. He also noticed a prominence. With this description of his condition, and without any physical examination, it was plain at once from what he was suffering: that the pain was evidently the result of the pressure of a large aneurismal sac.

When we came to measure the size of this aneurism we found that the disease had gained considerable headway. After being some time in the surgical ward the man was transferred, on February 13, 1879, to the medical wards, and at once placed upon large doses of the iodide of potassium, which was gradually increased in amount until ʒ i. (3.9) was taken three times a day; at the same time we kept him quiet. Under this regimen there was so much improvement in the pain, and decrease in pulsation, that the patient was able to leave the hospital and pay a visit to his family, but he soon came back again. Since then he has spent his time here lying quietly in bed, suffering occasionally from pain in the chest and left shoulder. There has at no time been any marked difficulty in swallowing, and on the whole, I think that the patient has been gradually improving, and becoming more and more comfortable. Our treatment has consisted mainly in the use of large doses of the iodide of potassium, which have been steadily kept up for months with an occasional intermission, for we have at times lessened the dose, but very rarely stopped it. The attempt was made upon several occasions to increase the amount taken beyond ʒ i. (3.9), thrice daily, but it gave rise to so much disturbance that we had to reduce it again. At present he is only taking gr. xx. (1.3). On the other hand, we have been giving gtt. v. (.40) of Fowler's solution three times a day, in combination with the iodide of potassium.

For a time, also, we employed the tincture of the root of aconite several times daily.

Since January 6th of the present year, we have made a change in our treatment, and are now employing, in addition to the iodide, ergot hypodermically every other day. At the same time we often find it necessary to give a hypodermic of morphia on account of the chest-pains, which occasionally give him much trouble.

Let us examine the physical phenomena, and let us see if we can modify them to any extent. You see that the patient is a well-nourished, strong looking man, whose chest is palpably deformed. The sternum has been displaced — pressed upward. There is an obvious deformity of the upper part of the chest. When we look farther, however, above the obvious deformity of the chest and the marked prominence of the upper part of the sternum, we find a local bulging extending from the clavicle to a spot below the third rib, which is the seat of a distinct pulsation. Below this pulsating body still, and striking nearer the nipple, is another seat of pulsation.

What attracts us at once in examining these two points of pulsation is that the second or lower pulsation is the more prominent of the two.

These are the physical signs of the case: a marked prominence under the left clavicle which pulsates, and below this point, nearer the apex, another pulsating spot not so prominent as the upper one, but pulsating with much more force. These facts have been confirmed by careful palpation practised in the wards.

"Does it hurt you over the prominence just under the clavicle?"

"No."

The pulsations, you see, raise my fingers perceptibly as I lay them over the spot.

When I percuss the chest, beginning to the right of the sternum at the upper part of the chest, the note is decidedly dull; it is so also as I cross the sternum, and until I reach and pass the pulsating prominence underneath the left clavicle, and come to a point on a line with the middle of the clavicle in the second interspace, there I get pulmonary resonance. I also find that the dulness extends below the nipple, where it becomes one with the cardiac dulness.

Upon auscultation over the upper point of pulsation, I can distinguish a systolic murmur of some length, but with no harshness and unconnected with thrill. A second sound (not a murmur) follows this systolic murmur.

Passing below to the second point of pulsation, I distinguish a faint systolic murmur over the cardiac region proper. This murmur becomes fainter and fainter as we go up toward the apex.

The second sound, heard over the cardiac region, is faint over the left ventricle, distinct at mid-sternum.

These are the signs upon auscultation as further phenomena connected with the circulation, let us pay some attention to the state of the vessels; taking first the left carotid.

"Hold your breath for a second."

An extremely faint murmur is perceptible over this artery. Over the right carotid the same extremely faint murmur is perceptible, a second sound can also be heard.

Upon comparing the two carotids, I should say that the murmur, although faint in both, is fainter over the left than over the right.

Now we will turn our attention to the pulses. How are they? The pulses on both sides are weak. I cannot say that there is any great and persistent difference between the pulses. The pupils are equal in size, and both of them are contracted. The right pupil responds a little less readily to light than the left. Just as I make this statement, the resident whispers in my ear, "Morphia last night." You may therefore take my statement as a correct observation with a somewhat doubtful explanation.

I will endeavor to see if I can detect any symptoms of pressure.

"Have you any pain in your chest now?"

"No, not near as much as I used to have."

"Have you any cough?"

"None at present."

He had a slight cough, and a little dyspnœa when he came into the wards.

"Have you any difficulty in swallowing?"

"No."

"Has your voice changed?"

"Not at all."

"Can you speak well?"

"Just as well as ever."

As bearing on these symptoms of pressure, let us see if there is any pressure upon the lungs.

"Take a full, long breath."

The respiratory murmur is distinct over both the right and left sides of the chest, anteriorly and posteriorly. It is even a little harsh over the right lung.

I will now examine the patient's back.

"Take another full breath."

The same state of things seems to hold posteriorly, except that the inspiratory murmur, which preserves a certain amount of harshness over the right lung, both anteriorly and posteriorly, is rather feeble over the back of the left lung.

If we add a few other symptoms, we shall have given a complete clinical record of the case. Let me say, however, just here, that while examining the back of the chest I could not distinguish any murmur over the course of the aorta, running my ear down the back, but that quite high up behind the site of the aneurism, I could distinguish a very faint systolic murmur.

"Put out your tongue."

The tongue, is, as you see, perfectly clean.

"Are you troubled with flatulence?"

"Occasionally, but not often."

There are no abdominal symptoms to speak of. The digestion is fair, and the urine normal. The finger-nails are slightly curved. He has never had any night-sweats. He is neither losing nor gaining flesh.

Let us put all these facts together, and see where we shall land in our endeavor to group the clinical phenomena.

The diagnosis of aneurism is very easily made. What symptoms point toward the existence of aneurism? First, a pulsation of marked character, different from that of the heart—the double centre of pulsation, if you like. This pulsation, too, is associated with a marked prominence. Pulsation at a prominent centre, different from the heart, is almost always significant of aneurism. This is the first symptom. Secondly, we have the systolic murmur, which occurs as the blood flows into the sac. This, also, is a pathognomonic symptom of aneurism, although this systolic murmur is absent in some cases.

This murmur is not associated with thrill. Is thrill a necessary symptom of thoracic aneurism? By no means, it is more usually absent than present. The absence of thrill, therefore, does not invalidate our conclusion that the case is without doubt one of aneurism.

While still speaking of these phenomena, let me call your attention to the fact that the position of the heart is displaced; its apex beat is higher up than usual; the organ is somewhat twisted about by intrusion of the aneurismal sac. I should say, too, that the left ventricle was hypertrophied, as there is a very marked increase in its power, force, and size.

The murmur which can be heard over the patient's heart is either a murmur transmitted from the aneurism, or else it is due to some coexistent valvular lesion.

Which is it? Since it is so faint, I should say that it was a murmur transmitted from the aneurism.

Still, looking at the symptoms of the case, I am struck with the feebleness of the pulse. I do not trust to my fingers alone in this case, but can show you the sphygmographic tracings which have been obtained. These wave-lines indicate great want of power on the part of the heart. This feebleness is remarkable, as there is such marked hypertrophy of the heart.

The pupils are about equally contracted. That this contraction is not wholly, if at all, the effect of the morphia which the patient took last night, may be gathered from the fact that there was the same contraction of the pupils before he took the morphia.

Do I draw any conclusion from the feebleness of both pulses and contraction of both pupils? Yes. The rule is this: when the aneurism occupies the right side of the arch, we have contraction of the right pupil and feebleness of the right radial pulse; the contraction of the right pupil being due to the fact that the aneurism presses on the sympathetic ganglia on the right side of the neck, while the pressure exerted upon the subclavian artery causes feebleness of the right pulse. As both pulses are equally feeble here, and both pupils equally contracted, the only deduction to be drawn is that both sides of the arch of the aorta are equally implicated. We have here, then, a very extensive aneurism, involving the right, transverse, and left portions of the arch of the aorta.

In looking over the man's history, we have what might be called a negative record with regard to pressure symptoms. There has been no difficulty in breathing or in swallowing. There has been no alteration of voice. As a general thing, pressure phenomena are the rule in thoracic aneurism.

The only sign of pressure here is upon the bronchial tubes. The respiratory murmur is harsh upon one side and feeble upon the other. Yet here this distinction is not so clearly made out as is often possible.

"Let the patient be carried out now."

I sent the man out because I wish to say some things to you which it would not be desirable for him to hear.

From the absence of signs of pressure, and from the marked character of the prominence, can we draw any other conclusions? Do these things throw any additional light upon the site and prognosis of the aneurism? Yes; they show that the aneurism tends to grow externally. If it were growing internally, we should have much greater pressure phenomena, and we should find the pressure phenomena much more marked now than they were early

in the case, whereas the very opposite of this is true. The aneurism is evidently growing externally, and what we have most to dread is that it will give way externally.

If this external rupture does take place, it will be by the absorption of the ribs and sternum. However, as yet it can only be a matter of probability. The sac is in contact with so many internal organs that it might rupture internally, but I think the chances are all the other way.

I have already called attention to the treatment, and told you that the patient had been very greatly improved by his year's rest and by the steady employment of the iodide of potassium. This treatment represents the best treatment in aneurism. It is a particularly useful treatment if, at the same time, we moderate the patient's diet, and so gradually bring the blood into the best condition for clotting. The iodide of potassium does good (1) by favoring coagulation and (2) by stopping the inflammatory processes in the sac.

What results have followed this treatment here? The very best. There is a very considerable clot within the aneurismal sac. If it were not so, we should have much more marked pulsation, a powerful beat, which we have not got. This absence of a strong pulsation is a proof that coagulation has gradually been taking place in the sac. The treatment is therefore accomplishing all that we could desire.

Other plans of treatment have been recommended and tried—such as galvanism, acupuncture, the steady application of ice, and the employment of remedies calculated to lessen blood-pressure, such as aconite and veratrum viride in decided doses. All these do good under certain circumstances, and I will refer to their use next Saturday, when I shall bring another case of much the same nature as this one before you.

In conclusion, I wish to state that we have relieved the short attacks of pain always met with in this disease by hypodermic injections of morphia. Chloral is a very excellent anodyne when the heart is not weak. It is rather indicated than counter-indicated by the lessening of blood-pressure present in this case.

Original Communications.

THREE CASES OF ANOMALOUS CARDIAC DISEASE.

Reported to the Cincinnati Medical Society.

By J. C. MACKENZIE, M.D.,

PROFESSOR OF PHYSIOLOGY IN THE MIAMI MEDICAL COLLEGE, AND PHYSICIAN TO THE CINCINNATI HOSPITAL.

Reuben T——, colored, native of Georgia; æt. 44; single; cook; was admitted to Cincinnati Hospital May 20, 1878. Mother died of dropsy; otherwise, so far as he knows, his family history is good.

He is a moderate drinker. Had some form of venereal ulcer on penis ten years ago, but never any secondary symptoms. Had rheumatism six years ago, which lasted ten months. Has had two or three attacks since, the last one three months ago. He states that for the last six years he has been subject to attacks of dyspnœa, and unpleasant sensations in left side, and, latterly, to palpitations, cough, and frothy expectoration. Some time since he spat up some blood. Has not lost flesh to any extent.

Present condition.—A man below medium height, of fair development, and well-nourished. Lips somewhat cyanosed; tongue clean; appetite fair; bowels regular.

Physical examination.—Area of cardiac impulse increased. Murmurs heard with both sounds, most distinct at base. The systolic murmur is very loud and musical, and can be heard over the whole front of the chest and in the course of the carotid artery and descending aorta. He was ordered ten drops of the tinc. of digitalis three times daily.

May 25th.—Complains of shortness of breath and palpitation of the heart, and rests badly.

June 1st.—The musical character of the sound no longer exists. The murmurs continue otherwise as before. 6th. The dyspnœa and palpitations continuing unabated, he was ordered ten drops each of tinc. of digitalis, and tinc. of valerian, and fifteen drops of tinc. of chlor. of iron, three times daily. 10th. Musical sounds have returned, otherwise no change. 20th. Condition is worse; respirations very frequent; has severe paroxysms of cough and dyspnœa. Is obliged to lie constantly on his back, and even in this position he rests badly at night. Has no œdema anywhere. To take, in addition to other medicine, a teaspoonful of syrup of morphia every four hours. 27th. The paroxysms of dyspnœa and coughing continue about the same; expectorates frothy mucus, streaked with blood; did not sleep last night, and had to sit up in consequence of the difficulty of breathing; it is less urgent this morning; musical heart-sounds continue; appetite fair; bowels moved twice; has had some œdema of the legs for a few days past. Is taking bimeconate of morphia and digitalis.

July 1st.—Has been reclining in chair all day; and feels pretty easy; cardiac dulness extends from the upper level of the third rib to the upper level of the sixth, and from the left parasternal line to the left mammary line; dyspnœa about the same. Morphia continued.

From this time until August, the condition remained much the same, except that the dropsy of the legs increased very much. It is rather remarkable that during his stay in the hospital his pulse was rarely above the normal in frequency. On the 20th July $\frac{1}{64}$ grain of atropia was given at night, but it did not relieve his breathing to any extent.

On August 2d, the swelling of his legs being very great, they were punctured in several places and a considerable quantity of serum flowed out during the next few days.

He steadily declined in strength, the orthopnœa being constant. The musical murmurs were replaced for two or three weeks before his death by the ordinary blowing sounds of valvular disease.

He died on the 12th August.

The urine was repeatedly examined, but only on one occasion was any albumen found, and then but a trace.

Autopsy made by Dr. N. P. Dandridge, pathologist to the hospital, eighteen hours after death.

Body fairly nourished. Rigor mortis slight; lower extremities œdematous. All the serous cavities contained serous fluid. Lungs œdematous, otherwise healthy. Heart much enlarged. Cavities dilated and contained large quantities of dark, soft, coagulated blood. Walls thickened; no valvular lesions. Kidneys quite firm; normal. Capsule everywhere readily removed. Liver on section mottled, and of a nut-

meg appearance. In some parts of the section an appearance as though blood had been effused into the tissue. Spleen small and firm.

Private D——, aged 34, German; single; admitted to the Cincinnati Hospital August 9, 1878. No hereditary disease, as far as he knows, in the family. Father died of typhoid fever. Habits temperate. Denies ever having had syphilis. States that he has had asthma for a long time, and that six months ago he began to have shortness of breath upon violent exertion. Has had palpitation of the heart occasionally. His present illness began one month ago with swelling of the legs. At the same time his urine became less in amount. The swelling has increased and the difficulty of breathing also.

Condition on admission.—A man of average size and fair development; apparently well-nourished. Legs much swollen and oedematous; tongue clean; appetite good; bowels regular. Wheezing sounds throughout the lungs; musical murmur with first sound of the heart, most distinct at the apex; area of cardiac impulse much increased. Ordered fifteen grains potass. bromide three times daily.

August 12th. Had great dyspnœa this morning; heart's action very tumultuous; skin cyanosed; pulse, 130. Whiskey was given freely, and he somewhat improved for a time; but at 12 o'clock he was greatly cyanosed, the dyspnœa was very urgent, and the pulse small and feeble.

He lingered, constantly growing weaker, until five o'clock the next morning, when he died.

His urine was examined, but no albumen found.

Post-mortem examination made ten hours after death by Dr. N. P. Dandridge, pathologist to the hospital. Marked œdema of the lower extremities. Lungs adherent throughout, and markedly œdematous. Heart very much enlarged, and walls thickened, especially those of the right ventricle. All the cavities dilated, containing soft coagulated blood. Valves normal. Pericardium contained serous fluid. Liver enlarged. On section, a large quantity of fluid blood flowed from it; it presented a nutmeg appearance. Kidneys firm, and somewhat enlarged. Capsule readily removed. Surface beneath smooth.

For the following history, I am indebted to Prof. William Clendenin, who was in charge of the case, and with whom I saw the patient in consultation:

John H——, Welchman, aged 58, carpenter, called at my office, August 13, 1878. He was a large muscular man, and presented the appearance of one suffering with ague. Skin sallow and dry; tongue somewhat furred; appetite poor and capricious; suffered with slight nausea after eating; bowels slightly constipated; complained of slight chills or rigors, and thought he had ague; pulse about normal.

I prescribed a mild mercurial purge, to be followed for four days by dilute nitro-muriatic acid.

Saw him a second time, August 19th. Tongue cleaner; bowels had been well evacuated; appetite better; he complained, however, of some distress at stomach, attended with some nausea after eating. I ordered him infus. quassiæ, ʒvi.; acid. muriat. dil., ℥ iss.; quiniæ sulph. ℈i., a teaspoonful after every meal.

The patient seemed to improve while taking this, and went to the country for three weeks. He came back feeling worse, and sent for me September 13th. I found him in bed, looking somewhat emaciated. Skin sallow; appetite very poor; some thirst; bowels costive; urine slightly diminished in quantity; specific gravity, 1020; no albumen; no sugar; some traces of bile; complains of having slight chills and a sensation at night of want of air, so that he required to open the windows. I ordered a more active calomel purgative, followed by gr. iij. quinæ sulph. every five hours, and gr. x. pepsinæ, and gtt. x. dilute muriatic acid after every meal. He was also directed to have frictions with salt water, and a diet of beef-tea, milk, eggs, etc.

September 17th.—Patient no better. Symptoms about the same as when last noted. Temperature at five o'clock this morning, 99½°. Still experiences the sensation of want of air at night. Has a loathing for food.

September 29th.—Patient frequently vomited small quantities of dark-colored mucus with food. Pulse, 86; heart's action quite regular; sounds normal; patient emaciating.

October 4th. Vomiting more frequent; no appetite; temperature, 99½°; bowels constipated; urine scanty.

October 14th.—Vomiting persists, particularly after taking anything into stomach; fluid ejected, dark, grumous, at times streaked with blood; refuses to take any nourishment, except at long intervals, and then only a little sweet milk; temperature this evening, 100½°.

From this time until his death, which occurred on the 29th, the patient gradually declined, no new features worthy of note having presented themselves.

A post-mortem examination was made the next day. The body was much emaciated, and the skin presented a slight icteroide hue; the heart was somewhat enlarged; the aortic valves were ulcerated and covered with fibrinous deposits; the mitral valve was similarly, though less extensively, affected; lungs œdematous; the liver was enlarged, firm in consistence, and a little rough upon the surface, it did not contain an unusual amount of blood; in the gall-bladder was found a gall-stone about the size of a hazel-nut; the spleen was much enlarged and rather soft; kidneys normal; stomach and intestines normal in all respects.

This case presents features in striking contrast with those of the other two cases reported. Whereas in them all the symptoms, both rational and physical, pointed to valvular disease of the heart, in this the only symptom having any bearing in that direction was the sensation of want of air which he sometimes experienced at night. I saw the patient, in consultation with Dr. Clendenin, on two occasions, on Oct. 1st and 8th, and on both occasions, the case being an exceedingly obscure one, we made a most careful physical examination of the heart and lungs, without, however, being able to detect anything abnormal; the heart was examined with particular care, in consequence of his complaining of the want of air, but the sounds were perfectly healthy. All the symptoms, with the exception of the one mentioned, indicated rather disease in the abdomen than in the thorax, and our opinion, although given with some reservation, was that there was probably carcinoma of the liver; such opinion being based upon the cachectic appearance of the patient, the slight icterus, some enlargement of the liver and induration of the organ, which we detected on palpation, the progressive emaciation and dyspeptic symptoms. The autopsy revealed our mistake, but it did not any the more enlighten us as to the cause of the digestive difficulties; for the increase of fibrous tissue in the liver, and the presence of a small gall-stone in the gall-bladder, were certainly not sufficient to account for them, and I do not think that the disease of the heart could have produced such an amount of con-

gestion in the digestive organs as to interfere with their functions without, at the same time, giving rise to such a hyperæmic condition of the lungs as would have resulted in serious disturbance of respiration, cough, and dyspnœa, which did not exist. How such extensive valvular lesions could be present in a heart without being attended with murmurs and the usual rational signs of cardiac disease seems to me inexplicable. I have never seen such a case before, nor have I ever met with the account of one in my reading. Were it not that our attention had been especially directed to the organ in consequence of the complaint that he made of want of air at night, it might be supposed that we carelessly passed over a murmur, which nevertheless was present, but, with the amount of care which we exercised, I do not think such an explanation admissible.

The other cases are equally inexplicable, but they presented the very opposite conditions, all the physical signs and rational symptoms of valvular disease were present, but nothing was found, post-mortem, to account for them. The circulatory disturbances might possibly be explained by the dilatation of the mitral and tricuspid orifices, and consequent insufficiency of the auriculo-ventricular valves; but those who saw the specimens expressed the opinion that such an explanation was hardly justified by the amount of dilatation present, and I do not think that it would at all satisfactorily account for the abnormal sounds, which, in the first case especially, were remarkably distinct. This case, before I took charge of the ward, had been under the care of Prof. John A. Murphy, and had been repeatedly examined by him as well as by Dr. Dandridge and others; indeed, the case was regarded, in consequence of the loudness of the musical note and the large area over which it could be heard, as a sort of show case, and was exhibited to, and examined by, an unusually large number of physicians.

I have reported these cases as illustrating, in a most interesting manner, the occasional uncertainty of physical signs. I do not wish to belittle the importance of physical diagnosis, but I think it is well that physicians should know that cases sometimes occur in which even the most careful examination and the existence of what seems to be the most positive signs will not prevent an erroneous conclusion.

ELONGATING HYPERTROPHY OF THE FEMUR AND TIBIA OF OPPOSITE SIDES (THE OSTEITIS DEFORMANS OF PAGET).

By W. H. DALY, M.D.,

SENIOR PHYSICIAN TO THE WESTERN PENNSYLVANIA HOSPITAL AT PITTSBURG, PA.: PHYSICIAN FOR DISEASES OF THE THROAT AT THE PITTSBURG DISPENSARY, ETC.

VOIGHT L——, aged four and a half years, a bright and interesting boy, the only surviving child of his parents out of five births, and the only child of this number of which I had the professional care in delivery.

The mother has been subject to inflammatory rheumatism for many years, but is otherwise healthy; she is small in stature, but of symmetrical build. The father is a large man of fine physique and usually healthy.

At the time of accouchement with this child the mother was suffering with a severe attack of acute articular rheumatism, chiefly in the hands and fingers. The labor was somewhat protracted, and the child at birth was extremely thin and quite delicate. In this child ophthalmia neonatorum of a severe type supervened early after delivery. Almost simultaneously, arthritis appeared in the child's right knee, attended with pain, swelling, and tenderness. This lasted about four months, the child having in the meantime recovered from the ophthalmia neonatorum and begun to thrive.

In the winter of 1879 the mother called my attention to the child having a painless, limping gait, but attributing this to some stiffness about the knee of the right leg, a sequel of the arthritis. Little attention was paid to it until Feb. 28, 1879, when I was requested to visit him for some slight ailment. Upon entering the room where he was, standing stripped upon a chair, in the process of being washed, I then observed that his right foot was advanced somewhat in front of its fellow, while the knee was slightly flexed, giving the right leg the appearance of being longer than the left. This led me to measure the limbs.

The right knee had, ever since the attack of arthritis in early infancy, been somewhat larger in circumference than the left one. The measurements were as follows:

February 28, 1879.

Right Leg.

	Inches.
From anterior superior spinous process to internal malleolus	$17\frac{6}{16}$
From anterior superior spinous process to upper edge of patella	$9\frac{4}{16}$
From upper edge of patella to internal malleolus	$8\frac{2}{16}$

Left Leg.

From anterior superior spinous process to internal malleolus	$16\frac{15}{16}$
From anterior superior spinous process to upper edge of patella	$9\frac{4}{16}$
From upper edge of patella to internal malleolus	$7\frac{11}{16}$

NOTE.—It will be observed that there is now apparently a difference of $\frac{1}{16}$ of an inch in the length of the limbs. Measuring from the anterior superior spine of the ilium to the internal malleolus, the right leg being $\frac{1}{16}$ of an inch longer than its fellow of the left side, there is a similarity in the length of the femora of both sides, while the tibiæ show the entire difference in length.

The child's general health is good. He is very active, both mentally and physically. A thick-soled shoe is ordered for the non-lengthened left leg to preserve the perpendicular axis of the body, and some cod-liver oil with phosphates ordered on general principles. Instructions are given to the mother to insist on the child bearing the weight of the body upon the lengthened limb as far as practicable, which can be done without the slightest pain, but is hardly ever accomplished, as the child, when standing, finds it more convenient to rest upon the short limb, and has a habit of resting the foot of the longer limb upon the instep of the foot of the short one by flexing the knee of the right leg.

April 10, 1879, about six weeks after.—The child is thriving and in most excellent general condition, and the following measurements are made and recorded:

April 10, 1879.

Right Leg.

	Inches.
From anterior superior spinous process of ilium to internal malleolus	$18\frac{3}{16}$
From anterior superior spinous process to upper edge of patella	$9\frac{9}{16}$
From upper edge of patella to internal malleolus	$8\frac{10}{16}$

Left Leg.

	Inches.
From anterior superior spinous process to internal malleolus	17 $\frac{1}{8}$
From anterior superior spinous process to upper border of patella	9 $\frac{3}{4}$
From upper edge of patella to internal malleolus	8 $\frac{1}{4}$

NOTE.—Since last measurement the child has made the remarkable growth in length of right leg in six weeks from 17 $\frac{3}{8}$ to 18 $\frac{3}{8}$ inches, 1 $\frac{1}{8}$, or about $\frac{3}{4}$ of an inch, and in the sound, or short leg, there has been a growth of $\frac{5}{8}$ or $\frac{1}{2}$ an inch

There is now a difference in the length of the femora of $\frac{1}{8}$ of an inch, while at the former measurement no difference was discovered, and it is to be presumed none existed in the two femora, and there is now a difference of $\frac{1}{4}$ of an inch in the two tibiæ, which showed the same difference in length at last measurement. Consequently, even allowing for unavoidable inaccuracies in measurement where the anatomical superficies are so movable and difficult to collocate, we can but conclude that the hypertrophic growth has lately been going on in the lower end of the right femur, and for the time-being it has been arrested in the head of the tibia of right side, and also in femur of left side there has been apparently no growth.

The case being practically of an entirely new character to me, I was naturally desirous of obtaining all the information I could upon it, and in seeking this end I happily learned that my friend, Dr. J. A. Lippincott of this city, had, while resident physician to the Pennsylvania Hospital, at Philadelphia, made and published some interesting records of a case in the *American Journal of Medical Sciences* for January, 1876, of a similar character, entitled "A Remarkable Case of Traumatic Hypertrophy (including Elongation) of the Digital Phalanges."

Dr. Lippincott courteously accepted my invitation to visit this patient with me upon July 31, 1879, when we made and recorded the following measurements, the child's health being as usual excellent, and bearing every evidence of physical as well as mental thrift and activity, and his body being of most beautiful proportions:

The measurements made by Dr. L. and myself were as follows:

July 31, 1879.

Right Leg.

	Inches.
From anterior superior spinous process of ilium to internal malleolus	18 $\frac{1}{2}$
From anterior superior spinous process of ilium to upper edge of patella	9 $\frac{1}{2}$
From upper edge of patella to internal malleolus	8 $\frac{5}{8}$

Left Leg.

From anterior superior spinous process of ilium to internal malleolus	17 $\frac{1}{2}$
From anterior superior spinous process of ilium to upper border of patella	9 $\frac{3}{8}$
From upper border of patella to internal malleolus	8 $\frac{1}{4}$

NOTE.—These measurements are made fifteen weeks after the last, and the lad has shown a growth of 1 $\frac{1}{2}$ or nearly $\frac{3}{4}$ of an inch in the limb which is the subject of the hypertrophic elongation. In the opposite or short leg there is a growth of $\frac{1}{8}$ or just $\frac{1}{4}$ an inch. In the right femur there is an increase of $\frac{1}{8}$ of an inch, and in the right tibia an increase of $\frac{3}{8}$ of an inch.

It will be observed that, with this strikingly rapid growth of the lower extremities, the left femur has not shown any elongating growth at all, but in the entire twenty-one weeks this part of the leg remains a measurel length of 9 $\frac{1}{4}$ inches, while the leg shows a growth of one inch, and entirely in the tibia.

The right femur shows a growth as opposite to this, in the same time, of 1 $\frac{1}{8}$, or nearly $\frac{3}{4}$ of an inch, while the right tibia exhibits a growth in the corresponding period of 1 $\frac{1}{2}$, or a little more than $\frac{3}{4}$ of an inch. So we observe while the right femur has grown, by its hypertrophic elongating process, very rapidly, its fellow has had its growth in almost complete arrest; and while the right tibia has shown a growth of 1 $\frac{1}{2}$ of an inch, the left has outstripped this growth by $\frac{3}{8}$ of an inch in the same period.

At the first measurement, upon February 28, 1879, there was a relatively greater length in the right leg of $\frac{1}{8}$ of an inch, or a little over a quarter inch longer than its fellow. At the second measurement, April 10, 1879, six weeks later, there was a relative greater length in right leg of 1 $\frac{1}{8}$ or $\frac{3}{4}$ of an inch longer than its fellow. At the third measurement, July 31, 1879, fifteen weeks later, or twenty-one weeks after first measurements were recorded, there was a relative greater length in the right leg of 1 $\frac{3}{4}$ inch, or more than $\frac{3}{4}$ inch longer than the left leg.

December 28, 1879.—Nineteen and a half weeks after the last measurement, and about ten months after the first measurement, I make and record the following:

Right Leg.

	Inches.
From anterior superior spinous process of ilium to internal malleolus	19
From anterior superior spinous process to top of patella	9 $\frac{1}{8}$
From top of patella to internal malleolus	9 $\frac{7}{8}$

Left Leg.

From anterior superior spinous process to internal malleolus	18 $\frac{1}{8}$
From anterior superior spinous process to upper edge of patella	9 $\frac{1}{8}$
From upper edge of patella to internal malleolus	9

NOTE.—We observe that the difference in the length of the legs now is only half an inch. Can this in any measure be attributed to the elevation of the short leg by means of a cork sole on the shoe of the left foot, thus breaking up the habit of the lad standing upon the left foot, and in fact compelling him to stand upon the longer leg.

We believe a measure of improvement has been brought about by this enforced superincumbent weight upon the right leg, and a gain of more than $\frac{1}{4}$ inch obtained.

We see there is a now a greater length by $\frac{1}{8}$ of an inch each in the femur and tibia of the right side over their fellows of the left.

There has, since last measurement, been a growth of the right leg of but $\frac{1}{8}$ of an inch, while there has been a growth of the left leg in the same time of $\frac{1}{16}$ of an inch, convincing us that the gain has been made by reason of the arrest in the vicious growth of the bone, and a corresponding increase of the normal development of the osseous structures. The knee of the right side is $\frac{1}{4}$ inch larger in circumference than its fellow.

The child is in vigorous health, as usual, and is growing broader; suffers no pain whatever in the limbs, nor has he complained of any since the subsidence of the acute arthritis in early infancy.

Remarks.—Sir James Paget, Bart., read a paper before the Royal Medical and Chirurgical Society,

November 14, 1876, describing four cases of this disease. One of these cases was under the care of Mr. Thomas Bryant, of Guy's Hospital, London, and is again reported in the volume of the Reports of the Hospital for the year 1877. The case is a remarkable one, nearly all the long bones of the body being involved to a greater or less extent, as well as the cranial bones.

Paget regarded the action producing this hypertrophy as essentially an inflammatory one. Taking the definition of this action as being simply "the production of imperfect structures," this might satisfy; but the fact that there is a vice in the appropriating power of certain tissues or localities in the subjects of this malady, can scarcely be denied, wherein inflammation has little to do.

In many of these cases there is a vitiated demand for pabulum. Or, if you please, the natural demand for material from the blood has become (in certain localities), of the bony structure, irregular, and consequently inharmonious growth results therefrom.

That inflammatory action exists, cannot be doubted in *some cases;* but in the LEFT tibia of the boy whose case I report, there is not, nor never has been, the slightest evidence of inflammatory action, of however slight degree. This action was confined entirely to the RIGHT knee in early infancy.

Dr. Lippincott observed his case in Feb., 1875, and reported it in Jan., 1876, while Paget reported his cases on Nov. 14, 1876, Dr. Lippincott having the honor of the priority of observation of nearly two years, and a priority of report of eleven months.

Mr. Bryant's case, as well as that of Dr. Lippincott, were supposed to be of traumatic origin; that of Dr. Lippincott beginning in the third finger of right hand, and was caused by a bruise from a stone falling upon the finger when the boy was two years old. A subsequent wrench of the finger was supposed to have increased the liability.

Bryant's case began after the patient was thirty-five years old, and dated from a fall while carrying a load upon the shoulders, the weight of the load coming down, striking the hip and injuring the pelvis of the man.

In Bryant's report of his case, he states the position of his patient was characteristic, with bowed back, falling head, drooping arms, and bent legs, giving the patient a simian or monkey-like aspect. This position was certainly characteristic in this case, but the disease is yet so rare, and the reports so few, that as yet it seems difficult to say what are the general characteristics other than hypertrophic elongation of the bones.

Bryant treated his case by starving the organic elements of the bone with the hope of encouraging the deposition of organic matter, but with little success, as the case was a progressive one.

Quoting Mr. Deeping's subsequent report from Southend, Essex, England, who had sent the case to Mr. Bryant, "the treatment was of no avail."

From the microscopic report made by Dr. Morris Longstreth, pathologist to the Pennsylvania Hospital, I quote the following concerning Dr. Lippincott's case. The doctor says: "After careful microscopic examination of sections of the bone, every portion appeared normal, both as to size and arrangement of its minute anatomy."

Cases of unsymmetrical growth of bones will doubtless be more observed in the future, that will be related more closely to excesses or hypertrophic development and be more or less dependent upon the condition of the blood or constitution, known as the ossific dyscrasia or diathesis.

This condition may be set about by inflammations, ulcerations, or attempt at repair after necrosis.

Yet, when all inflammatory action subsides, the co-ordinative appropriation of growth material may have been so deranged by the former inflammatory action as to start certain parts into hypertrophic growth, while other parts may cease to build up and their growth remain in arrest, though nourishment may go on as in bone of the completed adult growth.

The paper of Dr. Lippincott upon this subject is a most valuable contribution to medical science.

The case of Mr. Bryant, which began after the age of thirty-five, may not alter the rule, but it certainly forms a most remarkable exception to the belief of Dr. Lippincott, expressed in his paper, as well as the many valuable concurring authorities he cited, that all authors agree that it (viz., the disease in question) always takes place before the natural growth of the osseous tissue ceases.

Experience had really, as the doctor says, shown, before the publication of Bryant's case, "that the bones exhibit no tendency to undergo elongating hypertrophy after the developmental period is past. A further publication of cases may cause much more alteration in these views.

With your permission, I will quote from Paget to show that he had observed cases similar to the one I report, as early as 1870.

He says, page 62, third edition, "Surgical Pathology":

"There is a condition of bone so similar to hypertrophy in many respects, and so little different from it in any, that I may well speak of it here, yet not without acknowledging that nearly all I know about it is derived from Mr. Stanley.

"When any one of the long bones of a person who has not yet attained full stature is the seat of disease attended with an unnatural flow of blood in or near it, it may become longer than the other, which is the more healthy bone. . . . . And for all his life afterward he may be lame, and the character of his lameness will show that the limb which was diseased is too long."

I may, without impropriety, claim that I in this case observed what is quite worthy of notice, that while there was in the femur of the right, and tibia of the left side, an evidently rapid hypertrophic elongation, there was, at the same time, a corresponding arrest of growth in the left femur, as though the growth material had been diverted in a great measure from its appropriate destination or locality.

So far as the remedy for this condition is known, it is based upon the most rational therapeutic and mechanical laws.

The perpendicular axis of the body can be preserved to prevent in the growing youth spinal curvatures, or talipes; this can easily be done by building up the short side by means of a thick-soled shoe.

Nay, more than this has been done in my case, as —and to this I attribute the improvement—I have thrown the greater part of the boy's body-weight upon the long leg, and thereby gained a quarter of an inch by this means. As to medicines, those containing the elements of bone seem to me to be indicated, and it is needless to add that all health-giving measures are here demanded to restore nature's equilibrium in the anatomical formation of perfectly symmetrical structures.

GUMMATA OF THE PENIS RESEMBLING PHAGEDENIC CHANCRE.

By WALTER B. JOHNSON, M.D.,

HOUSE-SURGEON AT CHARITY HOSPITAL, N. Y.

C. K——, male, æt 32; single; United States; clerk; was admitted to Charity Hospital, N. Y., October 10th. He is of light complexion and somewhat anæmic; has generally enjoyed good health. He gives an obscure history of an attack ten years previous, of what was pronounced by the late Dr. Bumstead to be syphilis, he was treated rigorously for two months by Dr. B., he thinks, with mercurials. He was then treated by a Brooklyn doctor, who, after consulting his previous prescriptions, informed him that he would probably have a recurrence of his troubles, and would need treatment for some years.

At above time patient had a small sore on penis, with considerable discharge; had two suppurating buboes, which were opened by Dr. B. He was much weakened by this and subsequent treatment, and at that time also had a tedious abscess on neck. He has never had any cutaneous eruption, alopecia, iritis, osteocopic pains, mucous patches, or other syphilitic manifestations. Since that time he has had, on various occasions, numerous attacks of gonorrhœa, and also sores on his penis, which appeared from three to six days after coitus. These sores were treated and healed by the application of caustics.

Had his first coitus since January last. In consequence of his great liability to trouble, as shown by his history of previous attacks, he observed great care in cleansing the parts, and noticed no unusual symptoms.

October 7th.—He found a little drop of pus on clothing, which came from his meatus; at this time he had no pain. The discharge increased from day to day, and was attended by swelling of the penis, associated with severe pain in it and the groin. 10th. He entered the hospital; the discharge (urethral) was then a dirty yellowish brown color and very profuse. 11th. First saw a sore, which was situated on lip of meatus. Patient at this time contracted a severe cold, with stiffness in all his joints, and osteocopic pains; had pains in the glans penis, which were relieved by micturition. 13th. Glandular swelling and pain; decreased under simple treatment. 17th. Penis slightly swollen; a hardened, tender spot felt on glans penis, involving its entire lower half, which was the induration from sore in the urethra; outer margin of sore seen just at meatus and extending into urethra. The glands of the groin were swollen and painful, and about the size of a walnut.

Treatment.—Rest; application of carbolic and nitric acid.

October 21st.—A good deal of necrobiosis had occurred since last date. Put on:

Pil. mass hydrarg	gr. ij.
Ferri sulph. ex	gr. i.

One t. i. d.

Penis very sensitive to touch; applications of nitric acid were made on two occasions, and a tonic mixture, i.e., ferri et pot. tart., was given. 22d. A urethral fistula, formed by slough, opening into fossa navicularis at side of frænum. 23d. Slough increasing. Ordered hydrarg. chlor. mit. gr. ½ q., two hours. 54 of these powders were given; before the gums were touched they had a salubrious effect, decreasing the discharge, and rendering the pain less severe; anti-syphilitic treatment was then suspended, to allow secondary symptoms to appear, if possible. 27th. The sloughing is still present, but slowly progressing; considerable tenderness is felt along the anterior portion of urethra; has enlargement of epitrochlear glands. 30th. The phagedenic action is controlled. The slough cleared; nothing is left of the glans penis but two thin ales, the inner portion being entirely destroyed. The urethra is patulous, but there is now a feeling of induration in the urethral tract 1½ inches from the meatus, which is attended by pain and renewed discharge of pus, indicating that there is still some destruction of tissue continuing below the line of demarcation already formed, supposedly from the newly discovered indurated point. 31st. An endoscopic examination disclosed, at the point above mentioned, a spot of deep ulceration in the urethra.

November 30th. During the past month the treatment has been entirely tonic, despite which the patient has become cachectic, and was at one time slightly jaundiced; this, however, was relieved by brisk cathartics. The induration in the urethra has increased; the discharge is still present.

December 30th.—The patient has, during this month, developed on the dorsal surface and at the root of the penis, over the suspensory ligament, an hyperplastic mass, which is much more in appearance a cutaneous than a lymphatic enlargement, and has the feel of a gumma; he has also one of these in the right groin; they are about the size of hazelnuts.

January 1st.—As during the three months past no early syphilitic manifestations have appeared, a diagnosis of gummata of the penis was made, and the patient put on anti-syphilitic treatment, inunctions of ung. hydrarg., ʒ i. per day; and pot. iodid., gr. xxx., t. i. d., in increasing doses.

January 7th.—The hyperplastic material in each situation is resolving; the tenderness of the urethra, which was always present, has disappeared: the general condition is improving. 14th. The indurated masses are just perceptible; patient much improved; discharge and pain absent. 21st. The patient enjoys good health, has no indurated points, experiences no trouble whatever.

Attention is particularly called to the history of the appearance of the sore, which was, as the man is very intelligent and truthful, absolutely that of a specific infection—in period of onset, response to treatment, and all except the advance of secondary symptoms.

THE LEGAL AGE FOR MARRIAGE IN EUROPEAN COUNTRIES.—Austria: 14 years for both sexes. Germany: 18 years for males, and 14 years for females. Belgium: men, 18 years; women, 15 years. Spain: men, 14 years; women, 12 years. France: men, 18 years; women, 15 years. Greece: men, 14 years; women, 12 years. Hungary: Catholics and Orthodox, men, 14 years; women, 12 years; Protestants: men, 18 years; women, 15 years. Italy: men, 18 years; women, 15 years. Portugal: men, 14 years; women, 21 years. Russia: men, 18 years; women, 16 years. Roumania: men, 18 years; women, 16 years. Saxony: men, 18 years; women, 16 years. Switzerland, in the different cantons: men, from 14 to 20 years; women, from 12 to 17 years. Turkey: at puberty.—*Journal de Médecine, etc.*

NIGHT MEDICAL SERVICE:

A BRIEF STATEMENT OF THE PLAN OF NIGHT MEDICAL SERVICE IN ACTUAL OPERATION IN PARIS AND OTHER EUROPEAN CITIES, WITH A VIEW TO ITS INTRODUCTION IN NEW YORK.

By HENRI NACHTEL, M.D.,

OF PARIS, FRANCE.

(Read before the New York Academy of Medicine, February 19, 1880.)

I HAVE the honor to lay before this Academy for its consideration a summary of the plan of night medical service as adopted in Paris, believing that in New York, as in other great cities, grave accidents and cases of sudden and serious illness, that occur during the night, often do not obtain the prompt attention which they need. It is a well-known fact that there are many persons who have not a family physician, and who, in case of sudden and urgent sickness, lose much precious time before the needed medical help can be obtained, since the doctor may be absent or ill, or otherwise unable to respond immediately to the call, as will be seen in my *résumé* of the French reports on the night medical service established in Paris and other European cities. Having made inquiries as to whether such a service was in operation in New York, I was informed that nothing of the kind existed in this country, except that, in case of an accident occurring on the street, the police officer telegraphs for an ambulance to remove the patient to the hospital. But he has no instruction or power to send a physician to any person so injured, or taken suddenly sick at his private residence.

Would it not be a humane and excellent thing to have a night medical service established in New York on the same plan as in other countries? From a medical point of view it would be of great benefit to the profession, in giving us statistics of diseases occurring during the night in New York, as is done in Paris and other capitals in Europe.

NIGHT HYGIENE AND MEDICAL SERVICE.

Night in a physiological point of view.—The succession of day and night, and the meteorological changes which result, produce physiological modifications in the organism of living beings. The absence of sunlight, which is the cause of many of the changes that take place during the night in the atmospheric *medium*, invites man to repose and favors sleep.

Rest after the day's labor, and sleep—so essential to the repair of the organic forces—are two conditions which must be, above all others, taken into consideration in order justly to appreciate the nocturnal physiological phenomena.

Baerensprung, Froelich, Lichtenfels, Ladame, Mantegazza, and more recently William Ogle and others, have demonstrated that there is a nocturnal lowering of the temperature in man, due to the internal phenomena of nutrition.

If the temperature falls, the respiration diminishes—the respiratory movements being less energetic, and less frequently repeated (Becquerel), produce a depression of the organic forces, owing to the diminution in the production of carbonic acid during the night, and also, very probably, in great part, to the absence of the light.

This diminution of carbonic acid during the night, proved by several physiologists, evidently corresponds to the expression of the organic forces which takes place.

The experiments of Pettenkofer and Voigt show that during the night there is a large absorption of oxygen, making the quantity of this element much greater than during the day, and altering the proportion. They have observed that, in an adult twenty-eight years of age, the oxygen absorbed during the night amounted to 67 p. 100, while the carbonic acid exhaled was only 42 p. 100.

Night in a pathological point of view.—It is very easy to understand, after what has been said above, how much more exposed we must be during the night to suffer from the harmful influences that surround us, since the faculty of reaction is weaker than during the day.

In marshy countries and in damp localities there is nothing so dangerous as the evening fogs and dew. It is after imprudent exposure to their unfavorable influence that fevers generally present themselves. In the cities these fogs collect all the miasms and infectious germs that may exist. It has been, indeed, observed in a great number of cholera epidemics, that the disease generally made its appearance during the night.

In Munich, for instance, seventy out of a hundred cases have been recorded as occurring during the night.

But one must take into consideration another cause, namely, the evening cooling to which our organism is only too liable. Zimmermann has observed this injurious effect of night. "Cold nights," says he, "which follow warm days, are among the principal causes of the dangerous fever of Lower Hungary, where a great majority of the patients die."

During periods of excessive heat, it is nearly always after a nightly imprudence—such, for instance, as to sleep without sufficient covering—that diarrhœa and dysentery appear.

It is nearly always during the night that the first attack of asthma and gout appears. It is during the night that the fearful cough of a child affected with laryngismus stridulus comes to frighten the parents.

It is also then that the workman, who has spent all day far from his home, comes back to suffer the disastrous effects of his crowded rooms and confined air. How many cases of asphyxia have been the result of the accumulation of smoke in a bedroom, or of pernicious gases, or combustion which cannot find exit? And cases of poisoning by a leak in a gas-pipe, which has escaped attention during the night, are not infrequent.

Thus, certain flowers left in a bedroom sometimes have an evil influence on man's health.

Observation has proved that the most odoriferous flowers are the most dangerous. The lily of the valley, jasmine, tube-rose, and laurel-rose, among others, have produced accidents often fatal.

It is doubtless at the end of a day passed in expectation, anxiety and suffering, that despair, taking hold of the unfortunate, becomes the cause of the suicides which occur in the first part of the night.

NIGHT MEDICAL ATTENDANCE.

On different occasions, public attention in Paris has been called to the grave accidents and numerous cases of disease which had appeared during the night. Some of them were followed by death, because the help of a physician could not be procured. When, in 1869, a petition was presented to the senate in France, this body appointed one of its members to study the question. In the same year, Dr. Passant, General Secretary of the Medical Society of the Department of Charities, which, by the nature of its functions, had been able to study the question in a careful way, submitted for the first time to the Director of Public Assistance his project of night medical service, whose fundamental idea was the *utilization* of the police stations. This project, ac-

cepted in all its points by the director was about to be put in practice when the war of 1870 broke out. Two years later Dr Passant repeated his petition, and had the time the good fortune to see his project supported by Dr Nélaton. This gentleman, who had been commissioned by the senate in 1869 to make a report on the question, had decided to establish permanent police stations, in which he ordered an appointed doctor to be on duty all night, but acknowledged that Dr Passant's project by the very fact that it allowed the use of the police stations already existing, was more simple, more practical, and at the same time less expensive, and unhesitatingly abandoned his own notions to accept those of Dr Passant. But the bad state of his health, and soon after his death, did not allow him to give all his influence to this subject, and so, for the second time, the project of night medical assistance was laid aside. During this time Dr Passant's ideas made progress, and were accepted in foreign countries. The night medical service was inaugurated in Berlin in 1872, and two years later it was in operation in St Petersburg.

In 1875 Dr. Passant applied directly to the Prefect of Police, M. Léon Renault, who, understanding all the importance of such a project, adopted it almost completely, and in the month of November, 1875, presented to the municipal authorities of Paris a report on the measures to be taken.

I shall give here only an abstract of Mr. Renault's report:

"I believe I respond to an old and active public uneasiness in asking you to allow a new credit of 10,000 *francs*, for the purpose of insuring medical help to persons taken suddenly ill during the night. The cases in which the absence of such help has been fatal to patients are fortunately rare; still we occasionally see painful cases, whose reports, published by the press in a more or less exact way, only serve as an excuse for the most virulent attacks against the medical profession. . . . The work of doctors, which is among a thousand emotions and personal dangers, often in violation of all the laws of hygiene, makes repose at certain hours an absolute necessity for them.

"In another order of ideas, it is certain that the exaggerated fears of anxious families, and the uneasiness of the patients themselves, frequently expose the doctors to night-calls without sufficient reason. Indeed, they have a perfect right to be prudent, since more than once they have been betrayed and in danger of falling into traps laid by thieves who pretended to need their services for a patient. It is unnecessary to allude to the ingratitude of those patients who, after receiving the doctor's services, refuse him the most legitimate remuneration.

"These considerations explain the necessity for intervention on the part of the administration. This intervention will assure a threefold result:

"1st. That the person who may need the immediate help of a physician will know surely where to find one, and will not be exposed to the loss of precious time in repeated inquiries.

"2. That the physician himself will be able to respond promptly to the patient's call.

"3d. That the act of self-sacrifice accomplished shall not compromise his personal safety, and that he shall not be cheated of the just remuneration for his trouble.

"Doctor Passant, who is considered by the *préfecture de police* as one of its most devoted auxiliaries in his quality of chief physician (*adjoint du dispensaire de salubrité*), has occupied himself with this special question for several years, and has resumed his studies in propositions of a simple and practical character, which leave nothing to be desired.

"In each precinct physicians shall be invited to declare if they agree to submit to the calls which they may receive during the night.

"The name and address of those who have made this declaration will be inscribed on a board posted in the precinct police station.

"The person in need of a doctor will apply at the police station of his or her precinct, and will select on the board the physician whom he or she may prefer.

"A police officer will accompany the person to the doctor's house, and the physician to the patient's residence, and, the visit once made, will take him home again.

"On leaving him, he will give him a check for *ten francs*, which will be paid at sight by the cashier of the *préfecture de police*.

"According to the means of the patient, which will be subjected to investigation, the administration will demand the amount of the fee paid to the doctor; or, should the patient be unable to pay, the administration will assume the debt.

"It seems to me, gentlemen, that there is nothing to add to these resolutions.

"When they are sanctioned by your approval, they shall receive all necessary publicity to put them immediately into execution."

Soon after, a new notice, announcing the names of the physicians that had undertaken this service, for each one of the eighty police precincts in Paris, declared that this service would be started at 10 P.M., to close at 7 A.M., from the 1st of October up to the 31st of March; and from 11 P.M. to 6 A.M., from April 1st to September 30th.

"Doctor Passant informed the authors of the French Medical Encyclopedia (article Night, by Layet) that on the 6th of February, 1876, this night medical service was instituted in Paris, with the aid of 545 doctors. The number has since increased to 664, to the great satisfaction of the public and the physicians. . . . ."

The night medical service is established not only in St. Petersburg, but also in Moscow, Odessa, and Warsaw. It exists in Italy—in Rome, Milan, and Turin, where it has been organized by the exertions of Professor Facchioty. It has been started also in Lisbon. In France it will be shortly adopted by some of the largest cities—Lyons, Marseilles, Lille; it has been in activity in Algiers since March, 1878.

To Dr. Passant's project one point had been overlooked, on which, nevertheless, its author had particularly insisted, and whose importance could not be doubted, namely, that which relates to the possibility of establishing night medical statistics. This expectation has been fulfilled since the beginning of 1878. The following *bulletin*,* proposed by Dr.

---

* Precinct.
Ward.

PREFECTURE DE POLICE

PARIS NIGHT MEDICAL SERVICE.

BULLETIN OF STATISTICS.

Indicate the sex of the person to whom the services have been given . . . . . .

Age. . . . . Years, ... Months.

Business. . . . . .

Nature of the disease. . . . . .

PARIS. . . . . , 18

(The Doctor's Signature.)

Passant, where no mention is found of the name of the person who has needed the services, does not in the least wound the more or less exaggerated susceptibilities of doctors and families, in regard to medical secrecy.

In order to show all the interest that attaches to the result of such statistics, I could do nothing better than to present the author's quarterly statistical *résumè*.

From April 1st to September 30th, 1878, 1,913 visits have been made in the night-time. In the months of July, August, and September, there has been a difference of more than 131 visits; and the average of nightly visits has been 11 for the same three months. Men are in the proportion of 34 per 100, women 32 per 100, and children 14 per 100.

The character of the diseases for which medical attendance has been needed permits us to group them under several heads.

In a first group he places all the affections whose principal and alarming symptom is suffocation. They are, placed according to their frequency: bronchitis, angina, affections of the heart, pneumonia, pulmonary congestions, croup, and asthma.

In a second group, the diseases whose predominant symptom is abdominal, namely: gastro-intestinal troubles, cholera morbus, hepatic, nephritic, saturnine colics, attacks of dysentery, strangulated hernia, etc.

In a third group he finds all kinds of hemorrhage.

In a fourth, nervous troubles: convulsions, neuralgia, and neurosis.

In a fifth, congestions and cerebral apoplexy.

In a sixth, abortions and *accouchements*.

In a seventh, traumatic accidents: wounds and contusions, fractures and luxations.

In an eighth, cases of poisoning.

In the ninth and last group, sudden and accidental deaths and suicides.

Reports of Hospitals.

MEMORIAL HOSPITAL, ORANGE, N. J.

Service of Dr. WILLIAM PIERSON, Jr.

(Reported by Thomas W. Harvey, M.D., House-Surgeon.)

CARCINOMATOUS STRICTURE OF THE RECTUM.—LUMBAR COLOTOMY.

July 22, 1879. H. D., æt. 55; United States; hatter; single; no history of diathetic tendencies in the family. For the last six months has been suffering from a dull pain in the rectum. Four months ago constipation began, and has continued ever since, the movements gradually decreasing in size and becoming ribbon-shaped. For the last few weeks he has had no natural stools; they have been small, frequent, and associated with pain. Two months ago he was treated for hemorrhoids by injection of carbolic acid, with success.

Has been gradually losing strength and ambition to work, but has a good appetite and digestion.

Physical examination shows an annular rectal stricture, admitting the finger, about two inches above the anus, with thickening and infiltration of the rectal wall, beyond the reach of the examining finger. The surface of the bowel was ulcerated, and gave off a copious, bad-smelling discharge. The anus was also thickened and indurated. The inguinal glands of both sides were enlarged.

The patient had been admitted with the idea of extirpating the rectum, but the extent of the disease was considered as contraindicating that operation. The patient remained in much the same condition until August 10th, except that he did not have any evacuation of the fæces during that period. On that date vomiting commenced, and he ceased to pass gas by the rectum; the bowels became very much distended. He refused to take any nourishment, as the attempt to swallow produced colic and violent emesis. On the 12th he took a glass of wine and half a cup of milk without vomiting, and on the 13th a glass of wine. On August 14th, as his condition was becoming serious, Dr. Pierson, in the presence of the staff of the hospital, opened the descending colon in the loin. The operation was performed with the usual antiseptic precautions. As soon as the intestine was opened there was a copious evacuation of fæces and gas. The bowel was attached to the skin with silk, and the external incision was closed with silver sutures, leaving a place for an anus.

The patient reacted well from the anæsthetic, and made a very rapid recovery from the operation, his temperature never at any time exceeding 100° F., or his pulse 90. On the first day he had a very large discharge of fæces through the artificial anus, and from that time till his death he had a regular movement twice a day, the incontinence not causing much inconvenience except when he had a diarrhœa.

The wound healed up completely in three weeks, union being delayed by a small abscess that formed in the lower part of the external incision.

The union of the intestine to the skin was by first intention, and there never was, at any time, either retraction or prolapse of the bowel.

The man recovered so well as to be about the hospital grounds, and got along very well for three months, the rectal disease extending all the time, implicating the bladder, and accompanied by a profuse discharge. In December he became bedridden; the pressure of the growth caused œdema of the legs and scrotum, and the cancerous cachexia induced a constant loss of strength and flesh. There were cancerous deposits in all the glands about the pubic region, and many of them went on to ulceration.

From this time he gradually sank, worn out by the pain and discharge, and died January 27, 1880, five months after the operation.

The symptoms preceding death were progressive asthenia, with difficulty in swallowing, pain and tenderness over the abdomen, tympanitis, and suppression of urine.

Autopsy, January 28th, twenty hours post-mortem.—The abdomen was the only cavity opened. The peritoneum contained about a quart of serum, and was studded all over with small white tumors of cancerous growth. The omentum was transformed into a solid mass of cancerous infiltration one inch in thickness. The pelvis was filled by a large tumor, which was removed en masse. This tumor consisted of the bladder, with walls one-half inch thick, the rectum, and the sigmoid flexure of the colon. These, with the ureters, the vasa deferentia, and the large blood-vessels, were all bound together by the growth, and were closely attached to the pelvic walls. The rectal mucous membrane was destroyed and in its place was a dark surface of

ulceration, giving forth a profuse discharge and an abominable smell. The relation of the artificial anus to the intestine was carefully examined. The descending colon had been opened without injuring the peritoneum, making it a complete Amussat operation. This was easily demonstrated to every one present at the autopsy.

Orange, N. J., Jan. 4, 1880.

Progress of Medical Science.

On the Uses of Chrysarobin and Pyrogallic Acid.—In Hebra's clinic, chrysarobin has not fulfilled the expectations that were formed of it. It was noticed especially that when applied over extensive surfaces, in psoriasis, it frequently excited inflammation of the skin, and that after the subsidence of this inflammation fresh spots of psoriasis not unfrequently appeared on the very spots where the inflammatory action had been most intense. When applied to a circumscribed surface, however, the remedy acted well. On the face and head it could not be used, on account of the discoloration it produced. In other skin diseases than psoriasis, chrysarobin was not found to possess any advantages over other remedies. On the other hand, pyrogallic acid, which was first recommended for psoriasis by Jarisch, on account of its chemical resemblance to chrysarobin, proved in Hebra's wards very useful in the treatment both of psoriasis and of other cutaneous affections. It was used in the form of a ten per cent. salve, which was applied to the affected surface with a brush twice a day. The parts were then covered with cotton wadding or linen, or, when the affected surface was very extensive, the patient was enveloped in flannel. The results were always good, but the cure was attained somewhat more slowly than with chrysarobin, except in cases of widespread eruptions, when the latter would excite inflammatory symptoms. The acid very rarely produced any local irritation, and it caused much less discoloration of the skin than chrysarobin. No symptoms of poisoning were ever observed, although the acid could always be detected in the urine. The individual psoriasis plaques disappeared under its use in from one to three weeks. Three cases of herpes tonsurans were well advanced toward recovery after eight or ten applications. In this affection the remedy is preferable to soft-soap, because it does not irritate, and to Wilkinson's salve, because it has no smell. In two cases of lupus, also, pyrogallic acid salve proved very useful. The nodules were destroyed in three days, and cicatrization was completed in from one to three weeks under the use of an indifferent ointment. Syphilitic infiltrations were also removed rapidly by the same remedy, but it proved less efficacious in epithelioma.—*Berliner Klin. Wochen.*, Nov. 24, 1879.

Action of Nitrite of Amyl on the Vessels.—The statements of different observers who have studied the action of nitrite of amyl vary considerably, both with regard to the vessels affected—some stating that only the arteries, and others that all the blood-vessels, are dilated—and with regard to the degree of the dilatation. With a view to settle these disputed points, Dr. Gaspey, of Heidelberg, undertook a series of experiments on curarized frogs, with the following results:

1. Observations on the uninjured tongue showed that the action of nitrite of amyl on this organ is very marked and is developed very rapidly, and that it affects both arteries and veins. The effect of the drug was noticeable immediately after the inhalation was begun, and continued to increase for about two minutes. The duration of the action depended upon that of the inhalation. When this was continued about two minutes, the vessels returned to their normal calibre in from ten to fifteen minutes. The degree of the dilatation of the vessels amounted at most to one-third of the original diameter. The rapidity of the blood current remained about the same; in the first minute it often seemed somewhat increased, but always fell back soon to the normal point. To determine whether the nitrite of amyl acts also on already dilated vessels, the intact frog's tongue was irrigated with a one-and-a-half per cent solution of common salt, which, according to Thoma, causes dilatation of the vessels and increased rapidity of the blood stream. It was found, then, that the dilatation produced by the amyl amounted at most to one-fifth of the previous diameter of the vessels.

2. Observations on the intact web of the frog's foot showed the same changes as in the tongue during the inhalation of amyl, but the dilatation was less marked, although it appeared as soon and lasted about as long. The blood-current was at first more rapid, but soon became much slower, and sometimes the blood stagnated entirely.

3. Observations on the tongue, after it had been cut with a knife, showed the same changes in the vessels as in the uninjured tongue. Vessels that had been divided and had ceased to bleed under irrigation with the salt solution, began to bleed again when the amyl was inhaled. The migration of the white blood-corpuscles was not affected by the inhalations.

4. Observations on the mesentery showed the same changes as in the tongue. As in the web of the foot, the blood current was at first, and for a very brief period, more rapid, and then became for a time slower than normal.—*Medic.-Chir. Rundschau*, Nov., 1879.

Salicylate of Soda in Urticaria.—Although Heinlein has stated that urticaria is sometimes produced by salicylate of soda, Pietrzycki reports three cases of this affection that were cured by the same drug. A girl, eighteen years of age, had suffered for four days from a violent attack of urticaria, which was most severe at night, and had begun with a chill and fever. Quinine controlled the fever, but the eruption remained as before. The salicylate of soda was then ordered in doses of twenty grains three times a day, and after the second dose the eruption and itching had entirely disappeared. Two months later the same patient had another attack. Forty-five grains of quinine were given in divided doses without effect, but two doses of the salicylate again effected a complete cure. Another girl, twenty-one years of age, had suffered for two days from urticaria, which was most severe at night, and was attended by a chill in the evening. In this case, too, quinine proved useless, while three twenty-grain doses of the salicylate cured the disease entirely. The reporter believes that these three cases justify the assumption that the salicylate of soda, when given in sufficiently large doses, is a very effective remedy for urticaria.—*Medic.-Chir. Rundschau*, Nov., 1879.

Trichinæ in Fish.—Trichinæ were found in a pike that was recently caught in the North Sea, near Ostend. Dr. Clendenin, of Ostend, examined the flesh under the microscope, and found it full of the parasites. It is supposed that a shoal of this fish

had eaten the offal in the harbor of Ostend, and that the parasite had been conveyed to the fishes in this way.—*Med.-Chir. Rundschau*, Nov., 1879.

Cedron as a Substitute for Quinine.—Admiral Lapellin draws attention to a bean which is used by the inhabitants of Central America in the treatment of the cold fever, and which is said to be a good substitute for quinine. Dr. Coignard, who obtained the remedy in Puerto Arenas, Costa Rica, obtained favorable results with it, and Drs. St. Père and Quesnel found it even more powerful than sulphate of quinine. The bean is cut into bits as large as a pea, several of which are given in the interval between the paroxysms. This almond or bean is obtained from the simaruba ferruginea.—*Med. Chir. Rundschau*, Nov., 1879.

Subcutaneous Osteotomy for Genu-Valgum.—At the meeting of the *Société de Chirurgie*, on December 31, 1879, M. Terrillon read a report on the operation performed by Dr. Beauregard, of Havre, for the relief of genu-valgum. The operation, essentially that of Reeves (see Medical Record, Vol. XIV., p. 451), consisted in separating the internal condyle of the femur, by means of a chisel introduced through a small opening at the internal and lower portion of the thigh, then straightening the leg, and confining it in that position until union took place. The absence of all grave phenomena, and the rapidity of the recovery, rendered this a very interesting case. The result of the operation was rendered less satisfactory than was hoped for by the obstinacy of the patient, who insisted upon rising and walking on the fourth day, and upon leaving the hospital on the fifth. This operation has been performed in France by M. Beauregard only, and M. Boeckel (of Strasbourg). The procedure most favored in France is forcible straightening after the method of M. Delore, the danger from which is thought to be much less than that from osteotomy, which has induced severe arthritis, anchylosis, and even death. The reasons which led M. Beauregard to practise osteotomy were the youth of the patient—he was eighteen years of age—and the impossibility of determining the point of fracture in Delore's method. To obviate this objection, M. Terrillon has presented the Society an instrument recently constructed by M. Collin, by means of which the point of fracture can be accurately located, and the amount of force used regulated.—*Gazette Médicale de Paris*, January 3, 1880.

Elytrorrhaphy.—M. Le Fort reports three cases of elytrorrhaphy performed according to his method by a physician of Liege. One of the patients, a young girl, put her double vagina to frequent use, but the results of the operation did not seem to be impaired thereby.

M. Duplay states that he has performed M. Le Fort's operation twice with almost perfect results. In one of the cases, a woman fifty years of age, but still menstruating, no apparatus had been able to support the uterus in place. The cystocele was completely cured by the operation, but a certain degree of rectocele persisted.

Cysto-Fibro-Sarcoma of Muscle.—M. Gross, of Nancy, reports a case of cysto-fibro-sarcoma of the quadriceps. The tumor was removed once, but returned, and the leg was then amputated at the hip-joint. The femoral artery was ligated below the origin of the profunda, and the patient lost a good deal of blood. He recovered from the amputation, but died six months afterward with more than fifty secondary tumors in the lungs, liver, vertebral column, and cranial bones. The femoral artery bifurcated immediately below Poupart's ligament. M. Gross draws attention to the great rarity of primary sarcoma of muscles, the very existence of which has been denied by Cornil and Ranvier; Volkmann, however, has cited two cases of it, and this one makes the third on record. In discussing this case, M. Farabœuf said that surgeons should always disregard the statements of anatomists with regard to the point of origin of the profunda artery, and act as if it arose only a finger's breadth below Poupart's ligament.—*Gazette Médicale de Paris*, January 17, 1880.

Treatment of Cancroid by Chlorate of Potash.—An interesting discussion on this subject took place recently in the *Société de Chirurgie*, in Paris. M. Després opened it with an oral report on a memoir of M. Pilatte, of Orleans, on the treatment of epithelioma of the face by chlorate of potash. From a consideration of fifty-one cases, the author had arrived at the conclusion that the efficacy of the remedy is decided in cutaneous cancroid, but that it is useless when the process has involved the mucous membranes. Of eight cases treated by himself, five had proved successful and three were failures. M. Després, however, thought that there had been errors of diagnosis in the successful cases reported by M. Pilatte; that the disease, in his opinion, had not been true epithelioma, and, at all events, the cases had not been followed long enough to make sure that the cure was permanent. He believed that chlorate of potash had no curative power at all over epithelioma.

M. Ferrier stated that ulcerations of the face, resembling cancroid, are often met with in old men. Chlorate of potash often does good service in these cases, but it would be dangerous to rely on it in true epithelioma.

M. Le Fort cited a case of ulceration at the angle of the eye, which was thought to be epitheliomatous. It was somewhat inflamed, and while waiting for an opportunity to operate, poultices were applied. The ulcer healed rapidly under this simple application.

M. Verneuil observed that in all the cases reported as cured by chlorate of potash, the affection was not epithelioma, but polyadenoma of the sudoriparous glands. On the face, aside from syphilitic and scrofulous ulcerations, we meet with true epithelioma or epithelial papilloma, sudoriparous polyadenoma, and sebaceous polyadenoma, this last being very rare. The diagnosis of epithelioma is easy, and it is readily differentiated from sudoriparous adenoma, the points of election for which are the alæ of the nose, the forehead, and the eyelids. Epithelioma is not modified at all by chlorate of potash; sudoriparous adenoma, on the other hand, may disappear spontaneously, or it may often be cured by poultices or by chlorate of potash. He prefers, however, to cauterize the ulcer with chromic acid, on account of the greater rapidity of the cure.

M. Perrin said that the difficulty of diagnosis depended chiefly on the fact, that the tumors may undergo transformation. He cited the case of a man, aged sixty years, who had a sebaceous adenoma of the ala of the nose. This was cured in a brief space of time by acetic acid, but ten years later a true cancroid developed on the eyelid. He thought the sebaceous adenoma less rare than M. Verneuil claimed. —*Gazette Médicale de Paris*, Jan. 11, 1880.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 28, 1880.

ON SEVERAL MEDICAL TOPICS.

The late annual dinner of the Alumni Association of the Medical Department of the University of New York, was an interesting occasion in many respects. Not only was there gathered together a large number of the friends of the school—not only was the season, as usual, an enjoyable one—but many points were brought out in the toasts, a reference to which is of interest to the profession at large.

The President, Prof. Roosa, very appropriately opened the proceedings by an interesting address, giving the history of the organization of the Association, its rapid growth, and sketching its present usefulness and future work. The question of endowment, which lies at the bottom of true independence in teaching, was discussed with characteristic earnestness, and the hope was ventured—not in vain, we trust—that at no distant date the rich laymen may come to the aid of the colleges, by making them pecuniarily independent of the number of fees received from students. The question will then be, not how many students may attend a session, but what extent of scholarship may be reached.

Chancellor Crosby could not resist the temptation of wishing God-speed to the recent medical graduates. This was well enough as far as it went, and called forth a hearty response from all present. The less chance there is, however, for success, the greater the necessity for good wishes to that end. It is pleasant, nevertheless, to look on the bright side, and believe that there is room for all at the top. The applause which greets this sentiment at commencements shows how deeply it has taken root in the mind of the average student, and how necessary it is to make exceptions in favor of present company.

Prof. Loomis, in responding to the toast of the Medical Department of the University, took advantage of the opportunity to say a few words upon the much-hackneyed subject of medical education. The graded course did not meet with favor in his eye, and he believed that Harvard and the University of Pennsylvania would find their mistake. It was necessary that the student should keep the whole subject of medicine constantly before him. He should see the same cases over and over again, hear the same sounds, smell the same odors, and listen to the same principles. Preliminary education was quite necessary. It made better students, better doctors; but such well-trained men should be sent from the offices of the Alumni. When the Alumni would see that their own sons were graduates in the arts before sending them to study medicine, then the reforms so often desired would begin in the proper place—at home. The lengthening of the term to eight months each, for three sessions, was earnestly urged, and the necessary cooperation of the Alumni solicited. This suggestion is full of significance, and shows in what direction reforms will be initiated in the lecture term of the University. In fact, the necessity of such a change must force itself upon the various medical schools throughout the country. In regard to the abolishment of the graded system, few will agree with Prof. Loomis. It has not yet proved itself a failure. On the contrary, it is gaining friends every year among the educators of the country. Of course, such a system carried to an extreme would be disastrous to the student. While at the end of each session he should be examined only in the branches belonging to the same, he must not conclude that in his final examination for his degree he must not be prepared to review the whole range of subjects. The advantages of a graded system over the ordinary one are that a more systematic course of study is taken and a greater amount of time is allowed for attendance upon lectures. But the profession is being gradually educated to that point, and the various colleges over the country will soon have all the endorsement for the change which is necessary to establish its utility and insure its success.

Other speeches were made on the occasion referred to, but were of a more or less humorous and personal character, and necessarily treated of subjects of a comparatively narrow application. But Mr. John Foord, the editor of the New York *Times*, in responding to the sentiment of the daily press, gave his subject a much wider range. In speaking of the daily papers as disseminators of knowledge, he deplored the fact that the medical profession was so backward in allowing its light to shine before an appreciative public. The forcible and eloquent appeal which he made in favor of free advertising was calculated to carry conviction to the hearts of many wavering followers of the Code. In quoting from a recent editorial of the MEDICAL RECORD, he could not understand why it was so much the exception for the deserving medical men to get noticed by the daily press; why it was so common for such as are hardly second rate to have a

newspaper notoriety; and how the true dignity of the profession was best preserved by a modest silence. Of course, he assumed that the daily press was discriminative, and that the honor and dignity of the profession could be safe in its hands. Not that the daily press does not mean well enough to the profession, and would not do its utmost to see that justice is rendered; but, from the very nature of the case, this is impossible. The public are not yet educated to the point of knowing the difference between ordinary and extraordinary professional talent. The science of medicine is one by itself; and so many conditions have to be taken into account in estimating the value of a new method of treatment, the significance of a discovery in medical science, or the brilliancy of an operation, that an educated medical man is alone equal to the task. It is on this account principally that members of the secular press, who have at best a very superficial knowledge of medicine, are led into the error of so often mistaking men, who are considered merely second-rate by their peers, for the leaders of medical thought, the inventors of new systems, and the pioneers in scientific research. There are also many other reasons which are apparent enough to every medical man, why, in the present state of public opinion, the dignity of the medical profession is best preserved by a modest silence. The latter is very hard for some to do, who feel that the world should know of their works; but the majority of the profession are still content to labor and to wait. Our best men are not in need of patronage, having nothing to gain by increased publicity, and it has not yet been proven that the world at large has suffered as the result of a professional modesty that forbids the trumpeting of petty cures, or the heralding of so-called remarkable medical discoveries.

INANITION AT THE SHEPHERD'S FOLD.

THE occurrences at a charitable institution in this city, known as The Shepherd's Fold, have recently excited a great deal of interest and indignation. The discussion that was thus aroused has sufficiently covered the moral and legal sides of the question; and the thrifty Shepherd has been placed in the Tombs, there to meditate upon the disadvantages of his peculiar system of household economy. We may now, therefore, examine more especially the medical aspects of the case.

The Shepherd's Fold is an institution which takes in homeless children between the ages of two and sixteen, professing to rear them, educate them, and eventually find them places of employment. During the past year there have been between twenty and thirty in the fold all the time. On the 26th of December last, a boy of five years was taken to St. Luke's Hospital, where he was found to be in a condition that could only have been brought about by extreme neglect. An investigation followed, which showed that he was one of many who had been treated in the same way. The facts in regard to their diet were particularly extraordinary, and it is these which especially claim our attention.

There were twenty-four children at the Fold, ranging in age from two to sixteen. Four of the older ones, however, had extra food from various sources. For the other twenty the diet was as follows: at breakfast one cup of condensed milk, diluted eighteen or twenty times, was served out, together with rye bread. Sometimes, when the milk did not hold out well, corn-meal was added. For dinner two quarts of beans were made into a soup and distributed among the children. For the bean-soup an equal quantity of pea-soup or hominy was at times substituted. There was bread for supper. Twice a year, on Thanksgiving Day and Christmas, meat was furnished. No butter was supplied, nor any form of condiment or delicacy. The children lived on an exclusively spoon diet; indeed they had nothing but spoons with which to eat. The table was bare of a cloth, the children sat around it on soap-boxes, and if they wished any water, had to supply themselves from the adjoining wash-room.

The amount of food consumed each day by the children in the establishment was seven loaves of black bread, one pint of condensed milk, and two quarts of dried beans, or its equivalent in peas or hominy. To this may be added an irregular supply of corn-meal amounting to four cupfuls a day.

The medical testimony at the trial was unanimously to the effect that this amount of food, divided among eighteen or twenty children, would be insufficient to support life for any great length of time. It may be well to see how strongly facts substantiate such a statement.

Seven loaves of rye or black bread weigh $9\frac{3}{4}$ pounds. Taking the analysis usually given of wheat bread, and remembering that in rye there is more starch and less nitrogenous matter, there would be in the seven loaves, $\frac{3}{5}$ lb. of nitrogenous matter and $4\frac{3}{4}$ lbs. of non-nitrogenous matter, besides mineral salts and water.

In two quarts of beans, which weigh $3\frac{1}{2}$ lbs., there are about $\frac{1}{2}$ lb. of albuminous matter and $1\frac{1}{2}$ lbs. of the non-nitrogenous. In four cups of Indian-meal, weighing 1 lb., there are about $\frac{1}{4}$ lb. of albuminous and $\frac{3}{4}$ lb. of non-nitrogenous matter. In a pint of condensed milk there are 2.2 ounces of casein and 4.6 ounces of non-nitrogenous matter. The total daily amount, therefore, of water-free food for the twenty children was as follows:

	Nitrogenous.	Non-nitrogenous.
Bread, 7 loaves.....	$\frac{3}{5}$ lb.	$4\frac{3}{4}$ lbs.
Beans, 2 quarts.....	$\frac{1}{2}$ "	$1\frac{1}{2}$ "
Corn-meal, 4 cups.....	$\frac{1}{4}$ "	$\frac{3}{4}$ "
Condensed milk, 1 pint...	$\frac{1}{7}$ " (2.2 oz.)	$\frac{1}{3}$ " (4.6 oz.)
Total.....	$1\frac{3}{5}$ lbs.	$7\frac{1}{4}$ lbs.

Total of both kinds of water-free food per day, about 8 pounds.

Now, according to the estimates of Dr. Parkes, the amount of water free food per day necessary to the adult, under average conditions, is about $\frac{1}{20}$ of the body weight, or 15 oz. to every pound. An infant of six or eight months, weighing 20 pounds, would require daily 3 oz., and twenty children, averaging 50 pounds in weight, would require 9¼ pounds of water-free food per day. The actual amount given the children of the Fold was 1¼ lbs. less than this. Now, the average age of the twenty children was eight years, for which age a weight of 50 pounds is small.

There can be no doubt, therefore, that the amount of food supply was quantitatively deficient. It is to be remembered, further, that there were actually twenty-four children, besides Mr. and Mrs. Cowley, and some of the provisions here assigned to twenty children were often in reality consumed by the additional four. On the other hand, the children added to their allowance by begging on the street.

It will be noticed that the deficiency of food was quantitative and not qualitative, the proportion of plastic to non-nitrogenous matter being nearly at the proper rate of one to four or five. It is known that starvation from mere quantitative deficiency is very slow, while that produced by lack of a particular food element is nearly as rapid as when food is entirely taken away. This fact doubtless explains the condition of the children when examined. Only one boy had been sick during the past year. Fifteen of the children, however, were emaciated, more or less stunted in growth, had enlarged glands, and some form of skin disease or catarrhal trouble.

The case of Louis Victor, a child of five years, presented the results of an insufficient diet most typically. When brought to the hospital, he was emaciated and anæmic to the last degree, and the muscles of his back were so weak that he was bent over like a little old man. His weight was about seventeen pounds, and his height thirty-three inches. The average weight of a child of that age is about forty pounds; the average height thirty-eight inches. There were bed-sores on the child's back, and there was an ulcer on the ankle; his legs were œdematous. The stomach was irritable, and for weeks the child had had a diarrhœa. Great dulness and apathy of mind existed, and the child was at first constantly moaning and calling for something to eat. There were no evidences of organic disease, nor any traces of rickets. The emaciation and weakness had been undoubtedly aggravated by the chronic diarrhœa, but the general condition could only be attributed to the prolonged deprivation of food. Under the care of the hospital he has steadily improved.

We have gone over the chief points of medical interest in this case, and there is but one moralization which need be suggested by them. All accounts of famines show that the deprivation of food inevitably stimulates the worst and lowest impulses, and obscures every good feeling. The starving man becomes a beast, with but one desire, that of satisfying himself at any cost. It follows that, in attempts to cultivate the better qualities, to educate and improve children, the temporal wants must first be supplied. The beauty of holiness can never be felt by the famished. Innutrition is the direct antagonist of morality, and Satan can develop a world of wickedness out of a constant diet of bean porridge.

A LONG OR A SHORT CODE OF ETHICS.

At the meeting of the Councillors of the Massachusetts Medical Society, on February 4th, the committee appointed to draw up a code of ethics for the Society, presented majority and minority reports. The code approved by the majority was long and minute. It bore the evidences of extensive research in ethical literature past and present, and supplied directions for every emergency of conduct. The minority code, drawn up by Dr. Henry J. Bigelow, was very brief, and presented the general principles which should guide the physician in his relations with his patients and colleagues.

The debate upon the reports was highly interesting, and, at times, flavored with a little bitterness. Dr. H. I. Bowditch, referring to the minute directions in the majority report as to courteous and moral conduct, said that he had practised medicine for fifty years, and had never read a paper so derogatory to the profession. Dr. Cotting, who drew up the majority report, believed it impracticable to act on the basis that every doctor is a gentleman. And Dr. Bigelow would not wish the public to know that he belonged to a club in which it was necessary to make a law to the effect that its members shall not steal spoons.

The minority report and the short code were finally adopted by a considerable majority, a decision which will meet general approval.

The debate brought out a certain unpleasant fact which lies at the bottom of the whole difficulty. Nobody likes to say it, perhaps, but each one will individually admit, that some doctors are gentlemen, and some are not. The former do not need a code, and feel the indignity that a detailed and exacting one puts upon them. The latter do need a code, and the fuller it is, the better for them, provided it can be enforced. Committees on codes are thus placed in the embarrassing position of having to prepare a mixture which shall be at the same time astringent and laxative. They chose the wisest way out of the difficulty by offering the tonic of an essay on the general principles of etiquette and ethics. These, with some practical directions for the beginner, ought to be enough.

THE ANTI-VIVISECTIONIST MOVEMENT.

THE memorials to the legislature protesting against the anti-vivisection bill, and which are published in another column, are powerful appeals in favor of science and against maudlin fanaticism. It seems almost absurd that in the nineteenth century, and in face of its advanced civilization, that such a course on the part of representative scientific bodies should be necessary. But the anti-vivisectionists are too bigoted not to be enthusiastic, and what they lack in argument to prove their point they make up in misrepresentations. It is true this is the old story, but the profession must not lose sight of the possibility of the new bill becoming a law. The memorials to which we have already alluded are the expressions of the opinion of the entire profession, and our legislators should be made to feel their force by the well-directed and personal efforts of their medical constituents.

THE paper by Dr. Nachtel, in this number, will doubtless be the means of calling the attention of our readers to the workings of the medical night-service in Paris. In a future number we shall take occasion to allude in detail to the merits of the system.

WE call attention to the communication, published in another column, from the committee who drew up and presented the bill for the creation of a State lunacy commission. The arguments in favor of the bill are concisely given, and are altogether unanswerable.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 28, 1880.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

REPORT OF THE MICROSCOPICAL COMMITTEE.

THE uterine tumor, presented by Dr. John C. Peters at the stated meeting December 24, 1879, has been examined by the Microscopical Committee, and found to consist of unstriped muscular fibre and fibrous tissue. No evidence of either sarcomatous or carcinomatous tissue was found. Attached to the inner surface of the uterus, at its upper portion, was a mass of degenerating tissue about three-fourths of an inch in diameter. It had the gross appearance of a portion of a placenta, but the changes which it had undergone rendered microscopical examination unsatisfactory.

Signed,

W. M. CARPENTER.
T. E. SATTERTHWAITE.

SARCOMA OF CHOROID AND OPTIC NERVE.

DR. C. S. BULL presented a specimen of intra-ocular tumor removed by operation from a woman aged twenty-six years.

Sixteen months before, two days after childbirth, patient noticed that she was totally blind in left eye, and that the eye was abducted. Does not know how much longer the sight had been affected, as she had never noticed it before. The eye remained quiet and free from pain till six months before I saw her, since which there has been constant pain in eyeball, temple, and supraorbital region. When I first saw her the eye was slightly prominent, there was a beginning ciliary staphyloma upward and outward from the cornea; ant. chamber annulled; pupil dilated ad max, and edge of iris doubled back; lens lying against cornea, but transparent; no reflex from fundus; tension, +2.

Diagnosis.—Intra-ocular tumor, detachment of retina, dislocation of lens—V=O.

Enucleation.—At junction of nerve with sclera was found a thick, hard nodule of tissue, which surrounded the nerve, and was cut through with some difficulty. After removal of the eye this growth was seen to extend back immediately around the nerve for some distance, so as much of the nerve was removed with the surrounding growth as could be pulled forward out of the optic foramen and excised. The growth did not apparently extend into the orbital tissue generally

On opening the eye in the equatorial region a tumor of the choroid was found occupying the posterior two-thirds or three-fourths of the eye, pushing the retina before it, and extending through the sclera at the optic nerve, following the nerve and sheath as far back as it could be examined.

The tumor, exterior to the eye, has been examined and found to be white sarcoma, of the round-cell variety, though there were portions in the sheath of the optic nerve where there were many fusiform cells. This sarcomatous infiltration involved the nerve itself as well as the sheath, and in some places had produced pronounced atrophy of the nerve-fibres.

Position of growth not common—generally more anteriorly.

The vitreous was entirely absorbed.

HARE-LIP.

DR. POST presented a photograph of a double hare-lip, complicated with intermaxillary fissure and intermaxillary projection. The patient was a boy seven years of age. The intermaxillary bone extended as far forward as the tip of the nose, and the intermediate portion between the two lips was applied directly to the intermaxillary projection. An operation was performed, and consisted in separating the integument from the intermaxillary projection, then cutting away the projection, adjusting the inner margins of the lips, and using the integument between for the columna. There was a considerable flow of blood, some of which found an entrance into the trachea, giving rise to considerable obstruction in breathing. Toward the close of the operation respiration was entirely suspended for several seconds, necessitating the employment of artificial respiration by Sylvester's method.

SYME'S AMPUTATION FOR CARIES OF TARSUS.

Dr. Post also exhibited a foot which he amputated two weeks before, belonging to a girl aged fifteen years, on whom, during the month of March last, he had performed excision of the lower end of tibia, fibula, and astragalus. The ankle-joint had been severely injured while on a sleigh-ride more than a year ago, during the Christmas holidays. When the

patient was admitted to the Presbyterian Hospital, shortly afterward, all the parts about the ankle were penetrated by sinuses, through which there was a copious discharge of pus. During the operation of examination, the principal point of disease was found in the joint between the astragalus and os calcis. The os calcis did not seem to be carious, except a very superficial portion. The latter was scraped accordingly. An immovable apparatus was applied, and strong hopes were entertained regarding the healing of the wound. She left the hospital during the summer, and returned again during January. The disease had increased in extent, and Syme's amputation was performed. The whole os calcis was found in a carious condition. Patient has been doing well since the operation.

MULTIPLE GLANDULAR TUMORS OF THE NECK.

Dr. Post presented a glandular tumor of the neck, which was of interest in connection with the history of the case. The patient presented himself four years before, with an enlarged lymphatic gland on the same side of the neck, which gland was duly excised. Two years subsequently a similar growth appeared on the same side of the neck, and a few months ago a third tumor in same locality, each of which was duly excised. Strange to say, there had been no enlargement of the glands on the opposite side of the neck.

Dr. Post lastly exhibited a small lipoma from the arm of a lady. The peculiarity of the case was, that the growth was deeply imbedded in the fatty tissue of the limb.

BONY ANCHYLOSIS OF THE VERTEBRÆ.

Dr. Peabody exhibited a specimen of bony anchylosis of the second and third cervical vertebra, removed from an adult. There was no history obtainable, as the bones were removed at the same time with similar ones from other bodies, and the condition referred to was discovered accidentally, when too late to identify ownership. The bones were joined by these bodies, transverse and spinous processes.

Dr. Howe had seen two cases in living subjects in which there was good reason to suppose that such an anchylosis existed.

Dr. Post had seen the bodies of three vertebræ of the horse joined together by a bony bridge.

Dr. Putnam-Jacobi remarked that such a condition was frequently seen in arthritis deformans.

CYSTIC CALCULI—SPASMODIC ACTION OF GALL-BLADDER.

Dr. Putnam-Jacobi presented the gall-bladder and bile-ducts from a patient who, during life, had suffered, at intervals, from severe colic in the right hypochondrium.

The first occurred shortly after confinement with twins, succeeding to a painful pregnancy. The paroxysm was preceded by a severe purgation, occasioned by podophyllin, after which the patient had fainted. This first paroxysm lasted almost continuously for three days, and was followed by great soreness in the hypochondrium persisting for a week. At this time the patient was seen by Dr. Sands, who naturally suspected biliary colic, but hesitated to make a positive diagnosis in the absence of jaundice, symptoms of obstructions to the flow of bile, or the discovery of gall-stones in the fæcal passages. After this first attack, the patient remained free for two and a half years. Then, a few months before consulting me, she had another paroxysm, occurring after great fatigue. And, finally, a week before I saw her, she had suffered from a third, which came on during dinner, very shortly after the first ingestion of food. At the time I examined the patient, there was great tenderness, on pressure, in a limited part of the right hypochondrium, in the region of the gall bladder. No enlargement of this viscus could be discovered. The pain was said always to be exactly limited to the right half of the epigastrium, to be of the most violent and agonizing character, to last from half an hour to an hour or two, subdued only, with great difficulty, by chloroform, in fact, "seeming to wear itself out, rather than to yield" to the anodyne. Vomiting did not occur spontaneously, but once followed the inhalation of chloroform, and occasioned immediate relief. Without an anodyne the pain would last ten or twelve hours. During the last years of the patient's life, these paroxysms returned at irregular intervals, generally of two or three months; but occasionally they happened twice in one month. They nearly always occurred after a few hours of great fatigue, or of moral depression, and then came on so soon as the patient began to eat. In the later attacks the pain extended all over the epigastrium. Finding that the pain had been so speedily relieved by vomiting, the patient was directed to take an emetic of sulphate of zinc whenever the pain began, and with this the attack was always promptly aborted.

The events preceding the first attack (pregnancy, parturition, purgation, with an hepatic stimulant), as well as the form of the paroxysm, evidently pointed to gall-stones, which, from the negative symptoms, could not have descended below the cystic duct; on the other hand, the time at which the attacks occurred, their relation to eating and to fatigue, and the rapid relief afforded by vomiting, seemed to intimate that the colic depended, in part at least, on a spasm of the pylorus, excited by the first contact of food with the mucous membrane of the stomach.

The patient dying of a disease unconnected with the liver, the latter was carefully examined. The gall-bladder was found enlarged, adherent throughout to its fossa, not projecting beyond the free border of the liver, its mucous coat thickened and chronically inflamed, and its cavity filled with mucus and a mass of gall-stones, nearly all the size of a cherry-stone. One, however, was the size of a walnut, and lay precisely over the cystic duct temporarily occluding it. The duct itself, as also the hepatic duct and the communis, were all perfectly normal in calibre. It seemed impossible, in the absence of thickening or of dilatation of these ducts, that even the sand from the calculi could have been in the habit of passing through them. It seemed evident that so far as the colic depended on the biliary passages, it must have been due to spasmodic contraction of the gall-bladder alone; that the calculi only presented at the mouth of the duct, but had never really engaged in it.

The pyloric extremity of the stomach was intensely hyperæmiated, and the mucous membrane roughened as if from loss of epithelium. The rest of the stomach was rather unusually pale. There was no sign of gastric ulcer. There seemed reason to suppose that this condition would induce an irritable intolerance of the presence of food, that might lead to such a spasm of the pylorus as had been inferred. The relief afforded by the emetic would have been due, on the one hand, to the evacuation of the irritated stomach; on the other hand, to the throwing back into the gall-bladder of the presenting calculus. Since, normally, there is a close consensus of action between the pylorus and the gall-bladder, the bile

beginning to flow from its reservoir at the same time that the pylorus dilates *actively* to permit the passage of food, we may ask whether the chronic hyperæmia surrounding the pylorus were not the expression of a reflex irritation starting from the gall-bladder. The nervous connection between the filaments of the hepatic plexus and those other branches of the cœliac which supply the orifices of the stomach, is, of course, extremely close. Having once traced the history of such a case to its complete termination, it would seem impossible ever again to hesitate in the diagnosis of vesicular or cystic calculi, with a similar group of positive and negative symptoms.

THROMBOSIS OF AORTA.

Dr. Delafield presented a specimen of thrombosis of the aorta, with the following history:

A woman was admitted into Bellevue Hospital twenty-four hours before death, with a history that she had been suffering for four days with severe dyspnœa. Her breathing was very labored, her face was livid, the skin of her whole body was cyanotic, the radial pulse could not be felt at all, the pulsation in the larger arteries was very indistinct, and the heart-sounds could not be heard at all. She continued in this condition until she died.

At the autopsy the cause of the dyspnœa was found to be in the condition of the aorta just above the valves of the heart. The whole extent of the aorta was in an advanced condition of atheroma. Every here and there the inner surface of the vessel was roughened, and at such spots small coagula were adherent. Immediately above the aortic valve was a much larger coagulum of blood, forming a thrombus sufficient in size to completely close the orifice of the aorta at that point.

This was apparently the cause of the patient's death. The aortic valves themselves were not changed. The heart was normal, except some dilatation of the left ventricle.

He remarked that thrombosis of the aorta was not a very infrequent occurrence, but it was quite infrequent to have it cause death, as in the case presented.

Dr. Finnell presented the uterus of a prostitute who was supposed to have been murdered by strangulation, after having been struck upon the head with a sharp instrument. The specimen showed marked evidences of perimetritis and ovaritis. Dr. F. remarked that such conditions were common in women of that class.

MULTIPLE TUMORS OF THE CRANIAL, SPINAL, AND SYMPATHETIC NERVES WITH REMARKABLY FEW SYMPTOMS.

The President then presented mounted specimens of the above disease, with microscopic slides.

The following is the history of the case: M. D., 25; Canada; single; ladies' maid. Was admitted into the Presbyterian Hospital October 14, 1879. From her statements it was learned that at thirteen years of age she had small-pox, the attack lasting two months. During convalescence both lower extremities became paralyzed. Strychnia was given without apparent benefit, but the electrical current, in some form, proved useful, and she regained motion to some extent. Subsequently severe pain was established along the course of the sciatic nerves. The patient was free from uterine trouble, and gave no history of syphilis.

When admitted to the hospital she was found to have diminished sensibility in the right foot; motion also was limited. Under the continuous current she improved, however, and on October 23d was walking with greater ease; still, dull pain in the limbs was experienced at night. On November 1st she was taken with nausea and vomiting, and, subsequently, diarrhœa. This latter complication hastened the fatal issue, which took place November 4, 1879. Previous to death a large tumor had been detected in the right iliac fossa, and a diagnosis of sarcoma had been entertained.

At the post-mortem examination, forty hours after death, the *heart* and its *sac* were normal, both in substance and contents.

No pleuritic adhesions were found, and except that the lungs were œdematous, they exhibited no lesions upon either side of the spinal column, and along the line of the intercostal spaces chains of little bead-like tumors were seen. Their real nature was not at the time suspected.

On exposing the abdominal cavity, the tumor detected before death was found to embrace and include the cords of the lumbar and sacral plexuses, constituting a mass the size of one's head. So firmly was this new formation connected with the bone that the peripheral lamella was detached during the removal of the mass. Separating the growths, they were found to vary much in size; some were no larger than a pea; others were as large as a goose-egg. They were either on the sides of the nerve-cords, or pierced them centrally. The whole mesentery was studded with them, so that to the casual eye they looked like enlarged lymphatic glands.

The *spleen* was normal and quite firm; weight, four ounces. No tumors were noticed in the intestines. On the anterior surface of the *stomach*, just beneath the peritoneum, was a tumor the size of a walnut. The *kidneys* exhibited parenchymatous changes, but otherwise they were not abnormal.

The remainder of the dissection was carried out by Dr. Prudden, Lecturer on Histology at the College of Physicians and Surgeons, from whose notes the following description is taken: The spinal canal was opened, but no tumors were found within it. "The intercostals were thickened throughout and beset with numerous tumors up to the size of a small almond. Some of these extended through the intercostal foramina, which were enlarged. Small tumors were found on various branches of the fifth nerve, also on the occipital, spinal accessory, and phrenics. The lesion was most marked in the pneumogastrics, especially the right. This was thickly beset with tumors; the largest was ovoidal, and measured $4\frac{1}{2} \times 3$ ctms. The cardiac and œsophageal plexuses presented numerous small tumors, spheroidal or fusiform. The right sympathetic was also extensively involved. The left pneumogastric in the cervical portion was converted into a bulbed cord about as large as the little finger.

"As to the remaining spinal nerves in the extremities, they were all for the most part thickened, some extensively so, except in the foot and hands, where the change was but slight. Both sciatics, as they enter the thighs, presented themselves as immense knotted cords about 6×3 ctms., the right being slightly the larger. In the left leg all the branches of the sciatic down to the ankle were beset with larger and smaller tumors, as was the anterior crural with its branches. I counted on the left anterior crural and its branches 276 tumors, large and small. The lesion was more marked in the left leg than in the arm, though in the latter all the nerves down to the wrist were thickened and, especially above the elbow,

beset with numerous tumors. The tumors were abundant alike in the muscular and cutaneous nerves, perhaps, in general, more so in the latter. There were extensive changes in the muscles of the leg."

Dr. Pradden, unfortunately, was unable to examine any other portions of the body than those of which he furnishes a description. He promises to continue his investigations into the changes in the muscular tissue.

I was personally fortunate in being able to examine the tumors while fresh, and making use of osmic acid (one per cent.). I observed that the medullated nerves were very closely connected with the growths. Using this reagent, it could be seen that in some instances the medullated fibres passed directly through the centre of the nodules; in others merely skirted their periphery, or were expanded over them. These fibres evidently formed no considerable portion of the masses, and although it was found impracticable to decide whether they were increased in number, the impression produced by repeated examinations was that such was not the case, and that the change was in the connective substance of the sheaths. The tumors could not therefore belong to the myeline variety; nor could any considerable number of Remak's fibres be found, so that the neuromatous character of the growth was regarded as extremely doubtful. The presence of connective tissue was thought so plain, and the diagnosis of fibromata of the nerve-trunks was thought to be well proved. It is well known that most tumors of the cords are of this group. In such growths it is not uncommon for the myxomatous element to enter, and even others of the connective substance group, and this may be found to be true in this case.

Growths conforming to these gross anatomical characters have been described by Robert W. Smith, of Dublin, Townsend, and others; but one is often in doubt of the histological group to which they are to be delegated, as they are loosely described under the head of neuromata, fibrous tumors, myxomata, sarcomata, and the like. True neuromata are probably among the rarest tumors that are met with in any situation, and corroborative tests, many of the strongest kind, should be required before they are accepted as such. This case is remarkable and perhaps unique, as exhibiting extensive implication of cranial, spinal, and sympathetic nerves. The auditory and optic nerves were unaffected—a point which has always been observed. The symmetrical increase in the development of connective tissue explains, perhaps, why the symptoms were comparatively so insignificant. Thanks were due to Dr. W. H. Porter for the microscopical sections.

EXTIRPATION OF THE LARYNX AND ANTERIOR WALL OF ŒSOPHAGUS.

Dr. F. Lange presented a tumor of the larynx, with the following history: Mr. A——, of St. Louis, Mo., 74 years of age; previously of healthy condition; two years ago was first seized with periodical hoarseness, and soon after by spells of coughing, caused by small particles of food getting into the larynx during deglutition. In October, 1878, a tumor began to show itself on the upper edge of the right wing of the thyroid cartilage. On account of increasing dyspnœa, tracheotomy was performed at Chicago, in February, 1879. Since last July fluid food only could be swallowed; the patient lost much in general health and strength. His tracheal canula was not large enough to secure a sufficient amount of air, and he was much troubled by fits of dyspnœa, and even suffocation, from the passage of food into the trachea on every attempt to swallow. October, 1879, tumor had attained almost the size of an orange, was located on the upper part of the larynx touching the hyoid bone, dislocating the right carotid artery and pushing upward the base of the epiglottis, and everting it so that closure of the opening of the larynx was impossible. Deglutition grew worse rapidly, and on October 12, 1879, the operation was performed, consisting in removal of the tumor, including, with the exception of the lower part of the cricoid cartilage, the larynx, the right wing of the hyoid bone, and anterior wall of the œsophagus, which latter had, unfortunately, become involved into the disease. After three months of a very difficult and troublesome after-treatment, during which his life was in question more than once, patient left again for his home. By means of an artificial apparatus closure of the œsophagus was effected, deglutition was secured, and the patient was able to take his food without difficulty, and by means of an artificial larynx was able to articulate. Still, the apparatus was troublesome to him, and he did not care much about it. According to the last account, he was getting along tolerably well, more than four months having passed since the operation.

The tumor was essentially an extra-laryngeal one, taking its origin from the upper edge of the right wing of the thyroid cartilage, pushing downward the same, on account of the resistance of the hyoid bone, so that the supposed tracheotomy, performed formerly, had been thyrotomy, the tube passing just between the vocal cords. This explained the narrowness of the space and the difficulty in introducing the tube. The tumor had involved the mucous membrane, and especially the right false cord, and almost entirely blockaded the larynx. On the upper surface a horseshoe-like ridge could be seen, where the hyoid bone was in connection with the growth. On the right side the mass of the tumor had grown between the larynx and the œsophagus, pressing upon the latter and causing the trouble in deglutition. The epiglottis, of course, had also been removed entirely.

Dr. Lange stated that he had given a specimen of the tumor to a microscopist of this city, but that gentleman had not yet come to a conclusion regarding the nature of the growth.

Dr. Peaboby stated that he had received such a small slice of the tumor that it was impossible to discover its nature. In this connection, he took occasion to remark that it was quite important to give the whole of a tumor to a microscopist, in order that the true relations of different parts might be duly estimated. It was the microscopical examination of a growth as a whole that determined its true histological nature.

This opinion was concurred in by Drs. Satterthwaite and C. S. Bull.

Dr. G. M. Lefferts said: Having seen Dr. Lange's interesting case of extirpation of the larynx (the first operation of the kind performed in America, and the nineteenth upon record) in consultation, and, having had the pleasure of assisting him at his operation and of afterward watching the gradual process of cicatrization and final fitting of the artificial vocal apparatus, I am in a position to judge of the accuracy of his report, and to testify to the thorough surgical knowledge and manual skill which have done so much to conduct the case to its successful termination.

The chief point of interest, in cases of this class, lies in the indications for the operation; the latter is not, contrary to what has been sometimes asserted,

a difficult one to perform, and the question if whether the larynx shall be dissected out from above downward or from below upward, as insisted upon by the various operations, can well be left for decision to the pecularities which individual cases may possess. I have performed it both ways upon the cadaver, and find that it makes but little difference as far as the mere care of the operation is concerned. In Dr. Lange's case there was no room for question, as far as the indications went; a patient in hale condition, notwithstanding his sufferings, with a hard, dense tumor the size of a small orange blocking up completely the interior of the larynx, interfering with all its physiological functions, having long since necessitated the performance of tracheotomy, and now rendering deglutition, even of fluids, nearly impossible—this fact alone, according to Schüller, an overwhelming or vital indication certainly, nothing but death from starvation lay before the patient. It may be asked why was not a thyrotomy or a resection of the larynx performed instead of an extirpation? A glance at the specimen before you will clearly answer the question. When Czerny, in 1870, first devised this operation, and Billroth, in 1873, first performed it upon the living subject, it was supposed by some that in it lay a ready method of removing a larynx rendered useless for all physiological purposes by cicatricial contracture and stenosis, following syphilis, perichrondritis, from typhoid and the like, and replacing it by an artificial organ, thus overcoming the difficulties presented by this intractable class of cases; but the formidable array of deaths which have thus far followed its performance, for other causes have totally precluded any such idea, and it seems to me that we are to-day all agreed that it is alone applicable in cases of malignant or recurrent growth affecting the larynx; but even here a limitation must be made. All instances of laryngeal cancer are not proper cases for extirpation of the larynx. Have not the unfortunate results (thirteen deaths in nineteen cases) which have followed the operation sooner or later in the majority of cases so far reported been perhaps due, in great part, to an improper or hasty selection, to a non-appreciation of the true and safe indications?

The interesting question may, perhaps, be still further narrowed down. Is it ever a justifiable step to take, in even the commonest form of the disease—pharyngo-laryngeal epithelioma? It is impossible, by extirpation of the larynx alone, to eradicate the wide-spreading destruction, involving pharynx and neighboring parts as well as larynx; and Langenbeck's heroic procedure will hardly commend itself to any but the most venturesome surgeons. Can even primary laryngeal cancer, after its earlier and local stages, or when it occurs in the form of a diffuse cellular infiltration, be removed without question of recurrence. The statistics show us not. We are thus left with a single class of growth, and in this class have all the successes been made. Bottini, Foulis, Czerny, and now Lange, have extirpated for *sarcoma*, and the patients have lived. If, therefore, in the future, cases be more carefully selected, the above forms excluded, and, above all, the operation earlier performed, before the extension of the disease renders its complete removal an impossibility, I cannot question but that the results will be better. In the present stage of our knowledge, its utter condemnation in some quarters seems unreasonable. Have the other operative steps heretofore undertaken for this terrible disease shown us any better figures? Thyrotomy for the removal of malignant neoplasms of the larynx has been performed, according to Burns, some nineteen times, and in all cases, with the exception of one, was there recurrence in little over a year. Tracheotomy, it is well known, is but a palliative measure—prolonging life, it is true—but not meeting the ulterior surgical indication, and endo-laryngeal destruction of the growth has been but rarely attended with success, and then only when the small primary cancerous nodule has been dealt with. We are thus forced to an extirpation of the organ as the sole means which to-day presents a fair chance of saving life. If, however, better success is to be obtained, it must be in cases of *circumscribed* epithelial cancer; and through, as I have said, an early resort to the operation under such circumstances, will the extirpation become a much more certain procedure than the thyrotomy.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 5, 1880.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE Academy was called to order at 8 P.M., and the minutes of the previous stated meeting were read by the Assistant Secretary, DR. W. H. KATZENBACH.

The Corresponding Secretary, DR. JOHN G. ADAMS, made a report, and also presented an excellent portrait of the late Dr. Gurdon Buck.

Dr. Selden, of Canada, and Dr. Alden, U.S.A., were introduced to the Academy, and invited to take seats upon the platform.

Twenty-six new Fellows were elected.

DR. THOMAS T. SABINE read a memorial to the legislature, relative to *vivisection*, which was unanimously adopted.

DR. ISAAC E. TAYLOR then read a paper:

1. ON FLAGELLATION, OR SPANKING OF THE CHILD'S BACK, PREVIOUS TO ITS ENTIRE DELIVERY, AS A MEANS OF PREVENTING UTERINE HEMORRHAGE; AND
2. ON FLAGELLATION OF THE ABDOMEN OF THE WOMAN AFTER DELIVERY OF THE PLACENTA, AS A SUBSTITUTE FOR THE INTRODUCTION OF THE HAND INTO THE CAVITY OF THE UTERUS.

The paper was one sent up to the Academy by resolutions adopted in the Section in Obstetrics. The author spoke, in the first place, of the physiological function of the uterus, and the direct communication between its oblique sinuses and the vena cava. Frequently not the slightest warning was given regarding the occurrence of post-partum hemorrhage, either before or after the delivery of the child or the placenta, but suddenly the woman passed into an alarming syncope from profuse loss of blood. Under such circumstances there was no safety whatever except from instantaneous uterine contraction, and it was imperative that the obstetrician should be provided with, and should be ready to use, all possible means for the safety of the patient. He should possess calmness, courage, judgment, decision, and should be prompt to act; and if not thus fortified mentally, he should never, as Lee had said, "cross the threshold of the lying-in chamber." Dr. Taylor then referred to papers on the treatment of post-partum hemorrhage, read by Drs. Wilson of Baltimore, and Penrose of Philadelphia, before the American Gynecological Society, at its annual meeting in 1878—the former recommending the use of the hand as a curette to scrape the surface from which the placenta had been detached, and the latter the introduction of common

vinegar into the cavity of the uterus, on a piece of soft sponge or rag. Both papers, however, were written with reference to treatment *after* delivery of the placenta, but the method which he offered was simple, efficient, yielded results promptly, was always at our command and at a moment's warning, and was available not only in controlling hemorrhage after the delivery of the child, but also before and after the delivery of the placenta.

The plan was first to flagellate or spank the child's back moderately, rapidly, and repeatedly, after delivery of the shoulders, permitting the breech and the extremities to remain in the vagina, and the feet in apposition with or in the cervix uteri, and allowing them to remain there fifteen or twenty minutes, or even more. Pressure over the uterus should be avoided, for it might deliver the child before the desired object was accomplished, namely, firm contraction of the uterus.

The spanking should consist of quick, not harsh blows, and should be repeated until the child was delivered.

As soon as the uterus contracted firmly, and it was determined to complete the delivery, the uterine tumor should be seized with the hand and held until the placenta was delivered, and for some time after.

After the placenta was delivered, if hemorrhage occurred, expose the abdomen, and flagellate it with a towel doubled and the ends held in the hand, the doubled end being wet in cold water—ice-water, if it was at hand. The strokes should be powerful and quickly repeated. Should uterine relaxation follow the contraction, the method might be again employed, and repeated until other means could come to the obstetrician's aid in securing a fixed contraction. The method might seem harsh to the patient and to the attendants, but there could be no procrastination or temporizing in those sudden cases of post-partum hemorrhage. The remedy was limited to *primary* hemorrhage; that is, hemorrhage occurring independently of such causes as anæmia or malaria, or heart or kidney disease, etc. It was adapted to three classes of cases: 1. Those in which the uterus was large, soft, flabby, scarcely recognizable by touch; 2. Those in which the uterus was distended with blood—perhaps was as large as at full term of pregnancy; and 3. The smaller number of cases, that class in which the hemorrhage occurred in connection with alternate contraction and relaxation of the uterus.

Relaxation of the uterus might exist without hemorrhage, and concerning it we might not be able to give any satisfactory explanation. On the other hand, hemorrhage might be profuse when the uterus was firmly contracted.

Should the cause of relaxation with hemorrhage be a portion of the placenta, and the hemorrhage continue after it had been removed, then the hand might be introduced and used as a curette, according to the suggestions made by Dr. Wilson. Valuable as that remedy might be, however—perhaps absolutely necessary in certain severe cases—great care was required, judgment and gentleness, lest permanent injury be done to the uterus, or immediate damage, such as would increase rather than diminish the gravity of the complication. For removing the placenta, he had introduced his hand into the uterus but three times during the last thirty-five years, and in a large obstetric practice, and those were cases of complete adhesion of the placenta.

Dr. Taylor then quoted from a few authors regarding the usual method of managing the uterus after delivery of the child. Special reference was made to Ingleby, who said that to retard the descent of the child in ordinary obstetric practice was highly objectionable, since it would substitute "a process of art for a process of nature," and yet the same author reports one case in which he spoke of "gradual and slow delivery of the head separating the placenta without any hemorrhage whatever," in a case which had previously been subject to flooding.

Dewees did not introduce the hand into the uterus for the purpose of arresting post-partum hemorrhage, in a practice of thirty-five years, regarding it as not only unnecessary, but pernicious. He, however, recommended rubbing the os with the fingers, but not the inner surface of the uterus.

Cazeaux also recommended titillation of the os uteri for the same purpose. Both authors, however, recommended it as a measure to be adopted after delivery of the placenta, and both were chary of introducing the hand into the cavity of the uterus; and all authorities agreed that it was only when the os was contracted, or manifested a disposition to contract, that the introduction of the hand was efficacious. Dr. Taylor then gave his explanation, somewhat at length, of the manner in which his method operated. He also referred to the use of the cold-water douche upon the exposed abdomen, stating the contraction so secured was liable to be followed by relaxation, and that the agent, when employed the second time, was not usually as efficient as at first. Reference was also made to electricity, injections of hot water. Valuable as they all were, the delay might be too great before they could be used, and the life of the woman, as a result, might be sacrificed. A judicious combination of those measures might possess special advantages, and, if at hand, was not objectionable. The histories of five cases were then briefly related.

In this connection Dr. Taylor spoke of the use of anæsthetics in obstetric practice. He did not continue their administration at the close of labor in any case, regarding their influence at that time as unfavorable. The administration of an anæsthetic in cases of feeble uterine contraction—feeble from prolonged and tiresome efforts—usually stimulated the uterus to new action, which of itself was not infrequently sufficient to complete the labor without the aid of art.

THE PRESIDENT, in placing the paper before the Academy for discussion, remarked that he had been curious, since he read its title, to know what the aim and views of the author were, and what was the character and bearing of the paper. While listening to its reading he had discovered that the scientific interest was one point, and the originality of the suggestion another. Flagellation, however, as a therapeutical resource, the author of the paper did not claim as entirely original with him; and so it was not, for it was well known that, in Eastern countries and in the early ages, flagellation was resorted to to rouse the exhausted in all cases for the performance of those duties which led to results treated of in the paper. In harems, flagellation for the purpose of obtaining a corresponding response had been well attested; so flagellation was not an original suggestion as a therapeutic resource. But in the paper before the Academy flagellation had been considered with special reference to the saving of the life of the mother. He thought, however, that it should not be so restricted, but that it should also be referred to as an agent for saving the life of the child. For that purpose it was an agent that had been employed many years ago. Solomon recommended almost the same procedure for the sake of the child, as the author of the paper had recommended

for the sake of the mother; for, from his saying, "Spare the rod and spoil the child," the inference might be drawn that the use of the rod was for the sake of saving the child. Again, Solomon said, "He that spareth his rod hateth his son; but he that loveth him chasteneth him betimes;" also, "Chasten thy son while there is hope, and let not thy soul spare for his crying;" in which it seemed the therapeutics was not to be lost sight of, notwithstanding the crying. Now, it was not known that Solomon, while he seemed familiar with the therapeutical power of flagellation, ever was an obstetric practitioner, although he was credited with having contributed largely to obstetric practice.

Dr. W. R. Gillette regarded Dr. Taylor's contribution as a valuable addition to our resources for arresting uterine hemorrhage; and although, while an interne in Bellevue Hospital, he had seen the flagellation bring about contraction promptly in Dr. Taylor's hands, he had not, in two instances since then, been able to obtain the same satisfactory results. The principle was to excite the contractility of the uterus, but there were certain cases in which it was impossible to arouse it by the use of any stimulant. Nevertheless, it was a measure worthy of trial.

With regard to flagellating the child before complete delivery, it was an idea of which he had not heard, yet he could well see that it must necessarily have a rather limited application. We were not always able to prevent the complete birth of the child after the head and shoulders had been expelled. He had never attempted to retard a birth in the manner described, but certainly he should think the method could be adopted only in a limited number of cases, if under any circumstances it could be made available. He did not regard it as evidence that a woman would have post-partum hemorrhage simply because she had had such hemorrhage on occasions previously. In his own experience he had not met with uterine hemorrhage after delivery in cases in which he was expecting it. To be sure, he had been prompt in applying the ordinary precautionary measures, of seizing the uterus immediately that the head began to escape from the vulva, and keeping firm hold of it until the application of the binder. He also referred to putting the child to the breast as a means of exciting uterine contraction, it having served a good purpose in one case in which post-partum was threatened.

Dr. Montrose A. Pallen remarked that the measure which Dr. Taylor had brought forward for arresting partum and post-partum hemorrhage opened the whole field of the treatment of partum, ante-partum, and post-partum hemorrhage—a subject fraught with very great interest and importance.

He divided hemorrhages into those the result of faulty implantation of the placenta; those of partial separation of the placenta; those of laceration of the vulva, fourchette, perineum, or cervix uteri; those of inertia of the uterus; and those the result of systemic causes, such as renal and hepatic diseases, etc. In the treatment of hemorrhage we must of necessity seek for the cause, and if possible remove it. He was disposed to believe that when tedious labor occurred, in cases in which the pelvis and the distribution of the soft parts were normal, it was, in a majority of instances, dependent upon faulty implantation of the placenta. In a normal uterus at full term, with the placenta implanted in the central zone of the fundus, the uterine contractions were equable, and the force line, of necessity, was directly toward the os interum. If, however, the placenta be implanted upon one or other side, there was, upon the side opposite to the place of implantation, an increased quantity of force, and the direction from the fundus to the os interum was sigmoid, and several hours necessarily elapsed before the head engaged properly and passed into the excavation. Just in proportion as the placenta was implanted to one or the other side of the fundus, did prolonged labor occur, and just in proportion to the occurrence of prolonged labor was the woman prone to have hemorrhage. Under those circumstances, then, we must enter into the philosophy of the cause of the hemorrhage before we took into consideration the therapeutics. Direct irritation of the uterine structure by means of electricity, in cases of complete inertia, failure of the uterus to contract because the muscular fibre did not receive its proper supply of nutrient fluid, would, perhaps, be useless. Probably flagellation would be useless. Probably titillation of the lining membrane of the cavity of the uterus would be useless, and hot water would probably fail. But if the woman could be stimulated—if the waste, in a measure, could be repaired—if the nervous centres could be so aroused as to give rise to tonic contraction of uterine tissue, the woman's life might be saved, and for that purpose *nitrite of amyl* was the best known agent that could be employed. We must beget, in such cases, a hyperæmia of the spinal centres in order that the uterine fibres might maintain a tonic contraction.

Again, if the placenta was retained, the supposition was that the part from which it finally came was not in the tonic, sthenic condition, the uterine structure was ordinarily at full term, but that it was in a sodden condition, or at that point there might be a deficiency of uterine structure to contract over the vessels, which were patulous and gaping. When hemorrhage occurred under such circumstances, injections of iron or of iodine would be beneficial. The uterus contracted well, except at one point, and the injections would produce styptic thrombosis at that point, and thus arrest the hemorrhage.

Again, when we met with persistent hemorrhage, and there was firm contraction of the uterine body, we should examine the vulva, and, finding no blood coming from the fourchette or perineum, we should examine the cervix, and, finding it torn, the proper method to check the hemorrhage would be by means of styptic cotton held in place by a light tampon. That was the only form of post-partum in which a tampon was allowable, and it should be removed within thirty-six or forty-eight hours, and the parts thoroughly irrigated with carbolized water. He had, under certain circumstances, in that form of post-partum hemorrhage, been compelled to stitch the lacerated cervix in order to arrest the bleeding. After that form of laceration, septic fever very frequently arose, which had been confounded with the general so-called puerperal fever, but required only such treatment as was applicable to all wounds followed by surgical fever.

Again, hemorrhage might be due to œdema of uterine tissue, such as was found generally in the tissues of the body in connection with some cases of albuminuria. In that class of cases every measure might fail.

He thought that the recurrence of hemorrhage in cases in which the woman had, in previous confinements, suffered from flooding was in most instances due to the fact that in one labor the cervix was lacerated, and again lacerated during the next.

There being no further business, the Academy adjourned.

Stated Meeting, February 19, 1880.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE Academy was called to order at 8.15 P.M., and the minutes of the last stated meeting were read by the Secretary, Dr. Edwin F. Ward. The Corresponding Secretary, Dr. John G. Adams, reported the reception of a volume of the Transactions of the Medical Society of the State of New York.

A report from the Section on Surgery announced that Dr. Stephen Smith had been elected chairman, and Dr. A. B. De Luna secretary, for the ensuing year.

NIGHT MEDICAL SERVICE.

A report from the Section on Obstetrics announced that Dr. Salvatore Caro had been elected chairman, and Dr. Henry E. Crampton secretary, for the ensuing year.

The President introduced to the Academy Drs. Nachtel of Paris, France, G. W. Rohr of Rockford, Ill., and Dr. Griffin of Baltimore, and invited them to seats upon the platform.

The first paper of the evening was by Dr. Henri Nachtel, of Paris, and entitled "Night Medical Service." It was read by Dr. Gaspar Griswold, of New York. [See MEDICAL RECORD, pp. 229.]

THE PRESIDENT—The profession always has been and always will be the first to inaugurate any movement for the benefit of public health, and I think I may undertake to say that the public are now beginning to fully appreciate that fact. It is a matter of interest both to the profession and to the public, that every paper of this character should receive full consideration, and no doubt it will be accepted as worthy of the most earnest and careful study. I will call upon Dr. Gouley to open the discussion.

DR. J. W. S. GOULEY—Mr. President: The paper is sufficiently plain, as far as it gives the plan adopted in Paris and several of the capital cities of the Old World, and it seems to me that Dr. Passant's plan is so good that we should, at an early period, take steps to secure its adoption in this city. It would be a benefit not only to the public, but to the profession—at least in a statistical point of view. Again, there is nothing in its principle for the aggrandizement of any individual. It is for the benefit of the whole people and the whole profession. As already stated, several hundred in Paris have expressed their willingness to attend to any patient during the night. And it is highly probable that the same kind of night service can be secured here. I therefore offer the following resolutions with regard to this subject:

Resolved, That the thanks of this Academy be tendered to Dr. Nachtel for calling our attention to the necessity of more prompt and efficient medical succor in cases of sudden illness occurring at night, and of injury received in the streets.

Resolved, That Dr. Nachtel's paper be referred to a special committee of three academicians, to be appointed by the chair, and that this committee be instructed to investigate the question of "Night Medical Service" as it now exists in Europe, and report, at an early date, as to its practibility in the city of New York.

The President appointed as the committee called for by the resolution, Drs. J. W. S. Gouley, E. G. Janeway, and E. M. Bronson, and on motion the President's name was added.

DR. GEO. F. FRENCH, formerly of Portland, Me., has removed to Minneapolis, Minn.

Correspondence.

THE EYE-PARASITE—DRACUNCULUS LOA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The eye-parasite, which has received the names dracunculus loa and filaria loa, recently came under my observation at this place. The circumstances were as follows:

Native young man presented himself, complaining of a "sick eye." I examined the organ and discovered a white worm coiled up. Its situation was on the iris, beneath the sclera; but it was not at all confined, being capable of moving about and even obstructing vision when in front of the pupil. It was constantly in motion. The eye itself was bloodshot and inflamed, while the lachrymal discharge was profuse. I succeeded in extricating it in the following manner: holding the eyelids firmly open, the point of the small blade of an eye-knife was inserted between the sclera and iris, care being taken that one end of the worm was between the blade and sclera. The handle of the knife was then depressed so that the point would, in being carefully withdrawn, cause the end of the parasite to protrude through the opening in the sclera. This accomplished, it was easily seized and removed with a pair of ordinary dressing-forceps.

The filaria loa is, I think, quite rare, or at least is seldom taken out entire. If I am rightly informed, only one specimen has reached the United States; but the French are conversant with it. It *generally* selects the lower eyelid for its first appearance, though it is often found in the pinguis. If undisturbed it causes intense itching and stinging pain in the part occupied by it, which symptoms disappear in two or three days, caused, no doubt, by its death. It is not considered dangerous or even serious.

The specimen sent to America by one of the missionaries here was not entire, having been torn in the operation of extraction. The one in my possession is, I think, complete. I have it in a fifteen per cent. solution of alcohol, and will be glad to forward it for examination to any oculist who is sufficiently interested to study it thoroughly.

Very truly yours,
H. M. BACHELER, M.D.

AMERICAN PRESBYTERIAN MISSION,

THAT "QUESTION OF PRIORITY OF INVENTION" OF A HERNIAL SYRINGE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Dr. Wm. S. Janney, by his letter in the RECORD of the 21st inst., leads your readers to infer that he is the inventor of a hernial syringe, and that I have published the same as my own. I think, however, a brief review of the facts will place this matter in quite a different light. First, I wish to state, positively and emphatically, that I had no knowledge of Dr. Janney's syringe, or that he or any other person had ever constructed one resembling, in any particular, that which I described in the MEDICAL RECORD of the 7th inst. In that description I made no claim to originality. I shall now define my claims, viz.: a combination of prin-

ciples, most of which I believe to have been used before for other purposes, resulting in a hernial syringe. This combination is *absolutely my own*. My order for this syringe was given to Messrs. Stohlmann & Pfarre, 107 East Twenty-eighth street, about October 25th. I was led to its construction in the following manner: To Dr. George F. Shrady am I indebted for first suggesting that the point of the needle be protected. In discussing this matter with Dr. W. H. Philips of Ohio, that gentleman informed me that he had seen an aspirator-needle of peculiar design, the name of which he could not recall, which he believed would be a good principle upon which to make the hernial needle. That evening I chanced to find, in the possession of my friend, Dr. H. T. Hanks, the needle spoken of by Dr. Philips. I borrowed it and took it to the instrument-makers as a model. With the exception that it is smaller, the trocar-needle shown with my hernial syringe is an exact counterpart of this aspirator-needle, the originator of which I did not at that time know.

If I read Dr. Janney's letter correctly, he, in reality, only claims to be the originator of the trocar-needle, "an instrument similar in every respect as to the trocar arrangement;" although later he claims the whole instrument by saying, "This instrument that Dr. De Garmo represents in the cut is the *counterpart* of the one I have used. . . . I was very much surprised to see *my** instrument described."

If Dr. Janney's claim of priority is on the trocar-needle only, as I am confident it is, I would suggest to him that he give credit to whom it is due for the valuable principle involved in its construction: Dr. Simon Fitch, St. John, N. B., who introduced it first as the "dome-trocar," before the N. Y. County Medical Society, early in 1875.—*N. Y. Medical Journal*, April, 1875. And again, as "A Handy Aspirator."—*N. Y. Medical Journal*, November, 1877, p. 497. See also Tiemann & Co.'s Catalogue, part 1. p. 134; part 3, p. 102. Reynder's Catalogue, p. 89.

Very respectfully yours,
W. B. De Garmo, M.D.

116 East Thirtieth Street.

WIND SPASM.

To the Editor of The Medical Record.

Sir:—In your issue of June 28, 1879, vol. xv., No. 26, I find an article under the above caption, by Wm. J. Morton, M.D., and not having seen an account of a similar case either before or since, I am led to contribute one which I think is of the same nature, and which may not be without some interest to the profession.

In the fall of 1877, while attending a lady in this city for a slight indisposition, she informed me that her daughter was troubled with frequent eructations of wind, and wished to know if anything could be done to relieve her. Upon further inquiry, I found that she had been troubled with these spells, as she called them, for over six years, and that lately they had become so frequent and severe as to confine her to the house, not daring to go into society for fear they would come on, as they usually did, upon the least excitement. Her health was breaking down, she was losing flesh, had no appetite, and she feared that, unless a change could be brought about, some local disease might manifest itself, and she feared the result.

The young lady, on being questioned, expressed herself as follows (I use her own words, as far as I remember them): "When these spells are coming on, I feel a sense of fulness which begins just below the pit of my stomach, and gradually goes all over me, even to the tip-end of my fingers and toes, until I feel literally as though I should burst, and I can get no relief, either from loosing my clothing or change of position, until at last I commence to belch up large quantities of gas or wind, which will continue to come up sometimes for an hour or more, and which always leaves me in a weak and exhausted condition." She also informed me that it made no difference as to the kind or quantity of food she ate, and that they would come on sometimes just before meals, at other times just after, then again not for some hours after eating, and that they would sometimes occur during the night.

Having been under the care of several physicians, who had treated her for what they thought to be one of the complicated forms of dyspepsia, I thought myself that it might be one of the severer forms of the nervous type, and therefore treated her with the more common remedies, finally trying almost everything in the pharmacopœia that was suggested for such cases, but with no better success than my predecessors. At last, from my reading and observation of the case, I was led to try the sulphite of sodium, which I used as follows:

℞. Sodæ sulphis. ..... ʒ ix.
Aq. menth. pip. ..... ʒ iv.

S. One teaspoonful in half a wineglass of water, after eating.

This my patient took faithfully for two months. During the first two weeks she had four attacks, and there seemed to be no improvement; but after that time she made a steady and gradual improvement, the number and severity of the spasms diminished, she gained rapidly in health and spirits, and since the end of the eight weeks, although for a time after she continued to take the medicine every other day and in smaller doses, she has been entirely free from them.

Two reasons have prompted me to contribute this case to the readers of the Medical Record:

1st. As Dr. Morton suggests in his article, the rarity of such cases.

2d. The space of time which has elapsed (now over two years) since she left off taking the medicine, during which time, as she informed me a few days ago, she has not had a single attack, goes to prove, at least in this case, the efficacy of the sulphite of sodium.

In closing I will say that I lay no claim to a discovery, but am satisfied if, in reading this, some one shall be benefited or attain similar results by its use.

Yours respectfully,
D. N. Patterson, M.D.

Lowell, Mass., Feb. 12, 1880.

Examinations for Entrance to the Medical Corps of the Navy.—A board of naval surgeons will meet at Philadelphia on March 1st next, for the examination of candidates for the position of assistant surgeon in the navy. The officers so far detailed are Medical Director Edward Shippen and Surgeon Thomas N. Penrose.

LUNACY REFORM.

To the Editor of The Medical Record.

SIR,—The undersigned have had presented to the State Legislature a bill for the creation of a Lunacy Commission. An analysis of it has already appeared in your columns. It is desirable to have the approval and cooperation of the medical profession in the efforts to secure the passage of the measure, and we beg to present briefly some of the reasons to be urged in its support.

There are a number of facts relating to the care of the insane which are quite indisputably settled. Among these are

1. The rapid increase of the insane of the State, amounting nearly to one thousand a year. This is a greater increase, proportionately, than that of the population. Such a condition of affairs will soon compel the most careful study of the prevention, treatment, and economical care of the insane.

2. In many counties there are no arrangements for the early treatment of the acute insane, the majority of this class being not treated, but merely boarded.

3. A large proportion of the State insane are cared for in inadequate county asylums or poorhouses.

4. Apart from these facts, there are a number of points that urgently need full investigation. Among these are: *a*, the proper size of the asylums; *b*, the separation of the acute from the chronic insane; *c*, the proper mode of appointing officials; *d*, how to secure more medical assistance, and more scientific and clinical study in the asylums; *e*, the best medical treatment for the insane.

We consider it very clear that a proper answer to these questions would lead to a greatly improved system of asylum management.

5. There is absolutely no reason to suppose that if the matter is let alone, as is recommended by some, a reform will work itself out eventually.

6. The insane form a class which, above all others, needs to have a constant supervision, and an authoritative body to keep it in contact with the outside world. On this latter ground lunacy commissions have been founded and have proved very successful. The bill drawn up by us creates such a commission. It will devote its time to the supervision of the insane asylums of the State, and to a study of the problems in the care of the insane. It will have all the powers of the present commissioner of lunacy, with more independence, more working members, greater opportunities, and more executive machinery at its command. The bill introduces no innovations or experiments; it *adds nothing to the present expense* of the State government, and it does not burden the Executive with a new bureau.

Therefore we urge its endorsement by the public and the medical profession.

A MEMORIAL FROM VARIOUS MEDICAL SOCIETIES AND ASSOCIATIONS.

To the Honorable the Legislature of the State of New York:

Whereas, There is now before the Legislature a bill which is intended to prohibit, under the name of vivisection, the employment of experiments on animals for medical and scientific investigations; and

Whereas, Such prohibition would have a most injurious effect upon the cultivation and improvement of medical knowledge, and would be an obstruction to scientific discovery, and consequently a practical disaster to the interests of humanity; therefore,

We, the members of the New York Academy of Medicine; of the Medical Society of the County of New York; of the New York Medical and Surgical Society; of the New York Pathological Society; of the Albany Academy of Medicine; of the Buffalo Medical Association; of the Rochester Medical Society; of the Brooklyn Anatomical and Surgical Society; of the Elmira Academy of Medicine; and of the Medical Society of the State of New York, representing all the county medical societies in the State, beg leave respectfully to express our strenuous opposition to the proposed enactment, as contrary to the interests of the State and an enlightened policy of legislation.

Experiments upon animals have the same value for investigation and discovery in medicine as those in physics and chemistry for the corresponding branches of natural science; they have been, in

point of fact, a most valuable aid in medical research, and have often led to important discoveries upon which depends our knowledge of the human body in health and disease; they have made us acquainted with the functions of the internal organs, and the action of their different parts; they have brought to light a variety of methods and procedures for saving or prolonging life; they have been instrumental in the modification and improvement of important surgical operations; they have detected the cause and mode of transmission of contagious and infectious disorders; and they have been the means of introducing new and useful applications of medicinal remedies. They are not performed in such a way as to cause the infliction of unnecessary physical pain, suffering, or death upon the brute creation, but with due regard to its alleviation or prevention by every appropriate means. Their results, in increased knowledge of the living body, and facilities for its successful treatment and cure, in veterinary medicine, are of benefit to great numbers of the domestic animals, and are therefore of importance in increasing and preserving the animal wealth of the State.

The clause in the existing law, which recognizes the propriety and usefulness of such experiments, and expressly protects them from interference, was adopted by the Legislature in the session of 1867, after full and deliberate consideration; we regard it as a prudent, just, and humane legal provision; we offer our earnest protest against the present bill, which is intended to nullify its operation; and we confidently hope that no such unwise enactment will receive the countenance of the Legislature of the State of New York.

(Signed)

Wm. Manlius Smith, M.D., Secretary.

To the Honorable the Legislature of the State of New York:

The Faculty of the College of Physicians and Surgeons, Medical Department of Columbia College; of the University of the City of New York, Medical Department; of the Bellevue Hospital Medical College; of the Albany Medical College; of the Medical Department of the University of Buffalo; of the Long Island College Hospital; and of the College of Medicine, Medical Department of Syracuse University, having learned with regret that a bill has been presented to the Legislature, having for its object to prevent experiments upon animals for medical and scientific purposes, respectfully represent to your honorable body:

That the usefulness and value of these experiments in the study and improvement of medical science are established by the united experience and testimony of the medical profession; that they are of great importance in the teaching and demonstration of facts which lie at the basis of medical knowledge; that to interdict their employment would be, in our opinion, to obstruct and cripple medical instruction by depriving it of a valuable aid and by diminishing the means for imparting necessary information, and that it would consequently deteriorate the quality of medical education and the future efficiency of medical and surgical practice.

For these reasons we would express our strong desire that the present law, by which these experiments are duly protected, should be retained in full force and effect, and that no other should be enacted to interfere with them.

Alumni Dinner of the Medical Department of the University of the City of New York.—The ninth annual dinner of the Alumni Association of the Medical Department of the City of New York took place at Delmonico's, February 19, 1880, and was, in every respect, a successful affair. One hundred and twenty-five guests were present. The tables were tastefully dressed, and the bill of fare was ample and varied. A band discoursed appropriate music during the gastronomic performances. The following were the toasts, with their respective respondents:

The University of the City of New York, by Chancellor Crosby, D.D., LL.D. The Council, by Hon. John E Parsons, Esq. Our Alumni, by George K. Smith, M.D. The Medical Department, by Alfred L. Loomis, M.D. Our Sister Colleges, by F. N. Otis, M.D., and Lewis A. Sayre, M.D. The Pulpit, by

Rev. Chas. D. W. Bridgman, D.D. The Bar, by Hon. William Walter Phelps, Esq. The Press, by John Foord, Esq.

The President, Dr. D. B. St. John Roosa, occupied the chair, and, after a short address, introduced in a tasteful and humorous manner the various speakers.

The following officers were elected for the ensuing year:

For President, D. B. St. John Roosa (re-elected). *For Vice-Presidents*: Drs. William A. Hammond, John B. Dickson, J. J. Peterson, J. W. S. Gouley, W. E. Ford, Geo. K. Smith. *For Secretary*, Dr. Fred'k R. S. Drake. *For Treasurer*, C. Dixon Varley. *Executive Committee*: Stephen J. Clark, F. Le Roy Satterlee, A. E. Macdonald, Edward L. Parker, Andrew Otterson, R. A. Witthaus, L. Goldschmidt, Newton M. Schaffer, J. H. Hobart Burge, H. R. Conrad, R. A. Murray, B. D. Carpenter.

The Negro Thomas: Singular Control over Muscular Movements.—Dr. A. B. Miles gives an account, in the *N. O. Medical and Surgical Journal*, of the performances of a negro now exhibiting himself in New Orleans. The negro is a very muscular fellow. He claims to be without a diaphragm, and that his heart is movable. His great feat is the following: he lies on his back and stops breathing; the pulse disappears at the wrist, and the heart-beat apparently disappears from its normal position. A rhythmical pulsation at the same time appears in the right or left inguinal region, and this the negro claims to be his heart.

The explanation lies in the fact that the performer has acquired perfect and independent control of the respiratory and abdominal muscles. He takes a long breath, then suspends costal and abdominal breathing, at the same time exerts a slight inhalatory force over the heart, making its pulsations fainter. By strongly contracting the muscles of his forearm he draws the bicipital fascia tightly over the brachial artery, and thus stops the radial pulse. While in this state, which lasts but a minute, he causes pulsatile contractions of the abdominal muscles in the inguinal region. A pulsating tumor is formed, which he asserts to be the heart.

Prize Essays on Adulteration of Food.—In accordance with a resolution of the National Board of Trade, three prizes have been offered by that body for the best acts, accompanied by an essay, designed to prevent injurious adulteration, and regulate the sale of food and drink without imposing unnecessary burdens upon commerce. The essays must cover the general subject of adulterations, their effects, the best remedy, and an explanation of any legislation proposed. They must be sent before November 5, 1880, to the editor of the *Sanitary Engineer*. The Committee of Award is composed of Dr. J. S. Billings, Prof. Charles F. Chandler, Hon. B. Williamson, A. H. Hardy, and J. A. Gano. The amount of the prizes is $500, $300, and $200.

Laparotomy for Intussusception.—Dr. D. Pyle reports, in the *Nashville Journal of Medicine and Surgery*, a case of intussusception where laparotomy was performed; on the fifth day the patient recovered.

Death of J. Lockhart Clarke.—Dr. Lockhart Clarke died of phthisis on the 25th of January last. He was born in 1817, received his medical education at Guy's and St. Thomas's Hospital, and subsequently entered the practice of medicine at Pimlico. While engaged in general practice, he carried on the scientific studies and investigations which have given him a reputation and authority in matters connected with the nervous system, all over the world. He received a number of honors, being a Fellow of the Royal Society, and Physician to the Hospital for Epilepsy and Paralysis. As a practitioner, he never gained any great measure of success, but his scientific labors covered a wide field, and were marked by an originality and conscientiousness which did not fail to secure appreciation.

The Metric System and Microscopy.—At the annual address by the President of the American Society of Microscopists, Mr R. H. Ward, the adoption of the metric system was urged.

Dr. Henry M. Bullitt died at his residence, in Louisville, February 4th. He was largely instrumental in founding the Kentucky School of Medicine in 1850, and the Louisville Medical College in 1870.

The Late Professor Parkes on Tobacco-Smoking.—Dr. Parkes, at the request of Dr. Pratt, wrote a letter on the above subject, which has recently appeared in *The Lancet*. He says: "In conclusion, I confess myself quite uncertain. I can find nothing like good evidence in books; too often a foregone conclusion, without any evidence to back it, is given. I think we must decidedly admit injury from excess; from moderate use, I can see no harm, except it may be in youth."

Dr. Parkes refers to the fact that, while serving in Burmah, he used to see the Burmese women walking along the streets smoking a cigar, and carrying a child two or three years old, who also smoked his little cigar with the greatest gravity. Yet it was claimed by these people that tobacco never harmed them at all.

Recent investigations by Dr. Decaigne, of Paris, show that tobacco-smoking is quite injurious, to French women at least.

The Alienist and Neurologist is a quarterly journal, edited in St. Louis by Dr C. H. Hughes. It is intended that the journal shall occupy the peculiar province of furnishing the general practitioner with whatever is new and practical in matters relating to neurology and the allied sciences. The contents of the first number, and the list of eminent collaborators engaged, give promise of a very useful journal.

Books Received.

Sore Throat: Its Nature, Varieties, and Treatment etc. By Prosser James, M.D. Fourth edition. Philadelphia: Lindsay & Blakiston. 1880.

Answers to Correspondents.

Constant Reader, Richmond, Va.—Does the possession of a *medical diploma* by a man in easy circumstances, and who has *not* nor never has been a *practitioner* of medicine, entitle him to gratuitous medical attendance? Is it not the *duty* of the profession to charge such men for medical services, and collect the same as they would bills against others?

[Such a patient should certainly pay for medical services at the usual rates charged to persons of his means.—Ed.]

Original Lectures.

INNOCUOUSNESS OF CERTAIN HEART LESIONS—ACUTE ARTICULAR RHEUMATISM—SALICYLIC ACID AND ALKALIES.

A Clinical Lecture Delivered in Bellevue Hospital,

By AUSTIN FLINT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE, AND OF CLINICAL MEDICINE IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

(Reported for The Medical Record.)

Gentlemen:—When this man was admitted to the hospital he had general dropsy, cardiac hypertrophy with murmur, and pallor, but no dyspnœa, cyanosis, nor suffusion of countenance. There was no evidence of renal affection. The general dropsy was of cardiac origin. It has disappeared under the use of half-ounce doses of the infusion of digitalis administered every three hours. And we may now ask ourselves, what is the explanation of this man's good condition, with hypertrophy and valvular disease of the heart? When we read his history, we find the explanation in certain facts, which go to show that there is not enough cardiac disease to produce the dropsy; but that certain accessory circumstances, taken in connection with the cardiac lesions, produced it, and that these accessory circumstances being removed, the cardiac lesions alone remaining, the dropsy has disappeared. I think this case will prove a very useful one in illustrating what I wish to impress—namely, that certain heart lesions are so well tolerated that the patient makes no complaint of symptoms having reference to the heart, provided we can control all accessory circumstances which, added to the cardiac affection, produce certain effects, such as dyspnœa, dropsy, etc. That is the practical point which this case exemplifies. Naturally, an unfavorable prognosis is usually given in such cases as this.

Now, let us obtain the physical signs relating to the heart. The apex-beat can be felt in the sixth intercostal space, an inch and a half to the left of the mammary line, and there is a corresponding increase in the area of cardiac dulness. There is a murmur which begins after the second sound, and ends abruptly with the first, and is limited to a circumscribed space around the apex of the heart—a presystolic, or mitral direct, or mitral obstructive murmur. There is no other murmur. In this case, then, a certain degree of mitral obstruction has led to enlargement of the heart, and that hypertrophy and valvular lesion are borne by the patient perfectly well when in good general condition, but not when in the bad general condition to which his history refers; that is, he was anæmic, felt weak, was poorly nourished, and general dropsy, to a considerable extent, developed. But the repose of the hospital and the regular nourishment which he has received, and the digitalis—for he had a feeble action of the heart, just that condition which furnished the indication for the use of that drug, without salines, without alcoholics—apparently produced free secretion from the kidneys, which undoubtedly tended to cure the dropsical affection, and whatever of serious trouble proceeded from the cardiac disease.

I will now read the history of the case, and it will at once become apparent what the accessory circumstances were which contributed to the development of the condition which he was in when he entered the hospital.

He is twenty-four years of age, and a moulder by occupation. He says he never had rheumatism. I have had occasion to observe this particular murmur many times in patients who have never had rheumatism. He has been a moderate drinker for several years, but during the three months immediately preceding the development of the general dropsy, being out of employment, he went on "daily sprees," and was exposed to cold and all the vicissitudes incident to such a career. In that fact we find sufficient reason why a young man of this age should become sadly depreciated in vital force; and in it also we find the etiology of the factors of the condition associated with the cardiac disease.

The valuable practical lesson to be learned from this case is this: the danger from enlargement of the heart with mitral obstruction is estimated beyond the importance of those lesions. If this man has sufficient sense to enable him to appreciate the importance of regular habits of life, will abstain from the use of alcoholics, and do such work as he can do with comfort, that affection of the heart may be of service to him. The lesson is, that the cardiac affection is well borne, and may continue to be well borne indefinitely, if the associated circumstances do not produce an impoverished condition of the general system.

ACUTE ARTICULAR RHEUMATISM—THE ALKALINE TREATMENT AND THE TREATMENT BY THE USE OF SALICYLIC ACID—CARDIAC COMPLICATION.

Case II.—James C——, an Italian laborer, æt. 30, was admitted to the hospital January 23d. His mother died of causes unknown to him. He has five brothers living and healthy. His habits are good, and he has always enjoyed good health until three years ago, when he had an attack of rheumatism attended with great pain in the knees and feet, and the joints of both lower extremities were red, swollen, and hot. It was seven months before he fully recovered from this attack, and to his knowledge no cardiac lesion was developed at that time. On January 7th he began to suffer from pain in the right shoulder, wrist, and thigh.

Symptoms relating to the joints, such as were noticed in the previous attack, again developed. On January 17th he began to suffer from an "uneasiness" in the cardiac region, most severe at about the middle of the sternum. A physical examination revealed a mitral systolic murmur, soft and blowing in quality, and not conveyed into the carotids; and to the left of the nipple a pericardial friction-sound was heard. Salicylic acid was given every three hours in twenty-grain doses. Opium was administered in such doses as were necessary to relieve the pain and give the patient rest.

This case is interesting from the fact that there has been only one attack prior to this, and that we have no history of cardiac complication occurring at the time of his previous sickness. It is also interesting from the fact that he is going through his present cardiac complication with but little inconvenience, and with the effusion of so slight a quantity of fluid in the pericardium. In some cases the only evidence of pericarditis we have is the friction-sound, but it does not necessarily imply effusion of fluid. The dulness on percussion in the præcordial region is

most marked in the fifth intercostal space, to the right of the sternum. Now, to distinguish between pericardial dulness over an effusion of liquid, and enlargement of the heart, is an important point. It is done by physical signs. In enlargement of the heart the enlarged area of dulness is chiefly to the left of the sternum; it extends to the right of the sternum, but little beyond the normal situation of the right border of the heart. At the lowest point of this area, on the left side, the apex-beat is felt, or the first sound has its maximum at that point. On the other hand, the enlarged area of dulness from pericardial effusion extends more or less to the right of the sternum; the apex-beat, if felt, is above the lowest point of this area; the heart-sounds are distant, and the first sound is feeble, short, and valvular.

SALICYLIC ACID AS AN ANTI-RHEUMATIC REMEDY.

But to return to our clinical history: there is an important point in practical medicine to which I wish to direct your attention, and it consists in the use of salicylic acid as an anti-rheumatic remedy.

It seems to me that it should not supersede the alkaline treatment which has been employed to diminish the liability to cardiac complication. It has not as yet been proved that salicylic acid has any effect in the way of preventing cardiac complications except by way of shortening the duration of the rheumatic fever. I have had occasion to observe several cases of pericarditis occurring in the course of cases of articular rheumatism under treatment by the use of salicylic acid exclusively.

Because a remedy has been found that apparently causes the disease to abort occasionally, or, if not that, shortens its duration, we are not to relinquish the accepted alkaline treatment, but should carry it to its full extent as we have been accustomed to do heretofore. The alkaline treatment does not exert a marked effect upon the duration of the disease; but the weight of evidence showing that it diminishes the liability to pericarditis and endocarditis is overwhelming. Fortunately, the two plans of treatment do not conflict with each other.

ACUTE ARTICULAR RHEUMATISM—REPEATED ATTACKS—TREATMENT BY SALICYLIC ACID AND BICARBONATE OF SODA—NO CARDIAC COMPLICATION.

CASE III.—This case has certain points of interest clinically, and also illustrates the two plans of treatment referred to for acute articular rheumatism.

John M——, æt. 28 years, single, was admitted to the hospital on the 25th. His habits have been good. He does not remember any severe illness except rheumatism, from which he suffered severely five years ago. The attack began in the feet and soon extended to all the large joints. He was then confined to his bed most of the time for four months. This was a duration which, at present, we are unable to explain. Recovery, however, finally took place, and he enjoyed a good degree of health up to five weeks ago, when he was again attacked by rheumatism. He entered the hospital, and was discharged at the end of three weeks. He was out of the hospital three days, when he returned suffering from the present attack of rheumatism. When admitted, his temperature was 101° F; his urine was scanty, acid, sp. gr. 1034, but no albumen. The apex of the heart was beating in the sixth intercostal space, a little to the left of the mammary line, and there was a very slight mitral systolic regurgitant murmur. This murmur was recognized when he was admitted to the hospital five weeks ago, and is probably due to the rheumatic attack from which he suffered five years ago. But since his last admission to the hospital, notwithstanding the severity of the attack, it has not increased in intensity, nor is there any evidence of cardiac complication. In the early part of the renewed attack he was placed upon the use of salicylic acid in doses of twenty grains three times a day, and one ounce of the saturated solution of bicarbonate of soda. He has so far recovered—now, at the end of six days—as to be able to come up to the amphitheatre. He is receiving a nutritious diet and moderate doses of quinine, and doubtless what cardiac affection exists will prove innocuous if necessary conditions are properly controlled.

CIRRHOSIS OF THE LIVER, WITH HYDROPERITONEUM—ALL MEDICINES STOPPED—DIETETIC CHANGE.

CASE IV.—Owing to the fact that my hour has nearly expired, I will merely present this patient with special reference to one point in her clinical history. I will not enter into details, but at once say to you that she has cirrhosis of the liver, with hydroperitoneum. She has suffered from this affection more or less for some time, and the cirrhosis is clearly traceable to the great cause of that affection of the liver—namely, a certain method of using alcohol. Some time ago, three and a half quarts of fluid were drawn from the abdominal cavity by aspiration. I am inclined to think that that is the best method of removing fluid from the peritoneal cavity. She then took diuretics for a while. The aspiration was made on the 20th of November. At the present time, December 11th, there is but little liquid in the abdomen, and the point in the clinical history to which I wish especially to direct your attention, is what occurred between the date of the tapping and the present examination.

The diuretic mixture upon which she was placed after the aspiration, consisted of infusion of digitalis, sweet spirits of nitre, and bicarbonate of potash. For a time, the daily quantity of urine passed was increased, and then the apparently favorable action of the diuretic ceased. While the patient was taking the diuretic mixture freely, the daily quantity of urine discharged was 5, 12, 13, 12½, 10, 12, 17, 18, 16, ounces, and although an increase from what it was previous to the aspiration, the desired effect was not produced.

On December 1st *all medicinal remedies were stopped*, and the patient was placed upon a full milk diet. The quantity of urine passed during the next twenty-four hours was 19 ounces; and we find recorded 39, 36, 30, 56, 54, 50, 70, and 69 ounces as the quantities passed on the days immediately following. Under the influence of the milk diet, the quantity of urine passed daily was at once increased, and the increase has been sustained up to the present date. Before December 1st the patient took but little milk, and had only a poor appetite. Since that time her general condition and appetite have greatly improved.

In clinical medicine there is nothing more important than to call into exercise our best judgment regarding *discontinuance* of medicinal treatment. I have been made aware of the fact that there is danger of error in the medical mind in *two* directions: first, we may be over-confident with regard to the efficacy of medicines. There are those who have such unbounded confidence in the efficacy of drugs that they never see the natural course of a disease. This error should be avoided. The opposite error, also, is to be guarded against; namely, an over-distrustfulness

regarding the benefits to be derived by the use of medicines. In the treatment of all chronic cases it is an excellent plan to occasionally cease all medicinal measures, and study the effect produced. The withholding of all medicines, and the dietetic change, have, in this case, yielded the most satisfactory results. The patient is now taking six pints of milk daily.

AMPUTATION OF THE THIGH FOR SARCOMA OF THE HEAD OF THE TIBIA:

BROMIDE OF ETHYL AS AN ANÆSTHETIC IN CAPITAL OPERATIONS.

A Clinical Lecture Delivered at the Pennsylvania Hospital, February 4, 1880.

By R. J. LEVIS, M.D.,

SURGEON TO THE PENNSYLVANIA HOSPITAL, AND TO THE JEFFERSON COLLEGE HOSPITAL.

(Reported for The Medical Record.)

This girl, 20 years of age, has been admitted for a large growth, involving the upper part of the right leg, and gives the following rather indefinite history: about three years ago she observed a small tumor, situated just below the right patella, which she thinks may be referred to a fall in which her knee was struck. The gradual increase of the tumor, as well as the lancinating and burning pain of which it is the seat, have impelled her to seek treatment in the wards of the hospital. She says that her mother had a tumor removed from her thigh, which has not returned up to the present time, but our information as to this point is very meagre. The measurements, taken when the patient was admitted, one week ago, are as follows: the circumference of the head of the tibia, where the growth is situated, is twenty and a quarter inches, while the calf below measures eleven and a half inches, and the thigh above the patella thirteen and a half inches. The length of the tumor, from above downward over the convexity, is in the neighborhood of ten and a half inches. The growth projects forward, and the leg has been gradually flexed during the progress of the disease, so that she is now unable to extend it. The tumor feels elastic, and at points gives the impression of fluctuation. The inguinal glands are slightly enlarged.

The history of this interesting case is not at all definite, and we must depend on an examination of the clinical characteristics to determine the nature of the growth, and to decide on the manner of treatment.

That the enlargement is not aneurismal is evident from the fact that it does not occupy the position of the popliteal or anterior tibial artery, and has no pulsation or bruit. You must remember, however, that we do have, at times, pulsating tumors of an aneurismal character, situated in the head of the tibia, which have been denominated bone aneurisms, though they are usually associated with rapidly growing vascular tumors of a malignant nature. A glance shows that it cannot be a chronic synovitis of the knee, with hypertrophy of the osseous structures, because it is situated below the joint, and there is no fluctuation showing fluid in the synovial cavity. The patella is felt lying in its fossa above the tumor, is movable, and not in any way involved in the disease. The growth, in fact, evidently involves the head of the tibia, and apparently that bone alone. It is a matter of moment to determine whether the tumor is benign or malignant. Surgically considered, it is of little use to speculate upon the microscopical structure of the tumors presented for our consideration if the malignancy of the growth is once proved. The clinical characteristics of malignant growths are, as a rule, involvement and infiltration of the surrounding structures, implication of lymphatic glands, and more or less rapid increase. If such aspects are furnished, the surgeon looks upon the disease with suspicion.

Here the growth has not been very rapid, and the pain not severe; the glands are only slightly involved, which may be due to mere sympathetic irritation, and no marked infiltration of the soft structures above and below exists. The most malignant forms of disease seem, therefore, to be eliminated, and the diagnosis becomes narrowed down to enchondroma, fibroma, and osteo-sarcoma of some variety. It is not always easy to distinguish these tumors, but the elasticity observed on palpation, the indistinct fluctuation, and the size and form of the growth, together with the age of the patient, have seemed to point to the diagnosis of sarcoma of the tuberosities of the tibia, undergoing, perhaps, cystic degeneration. Such cases are not uncommon, for in this hospital a number of cases of sarcoma of the lower jaw and other bones have been repeatedly presented at the clinic.

The treatment proper for this case is very evident. Whatever be the nature of this semi-malignant and increasing tumor, the indication is to get rid of it by amputation above the knee, as soon as possible, in order to prevent the breaking down of health accompanying the progress of such diseases. It will be necessary to amputate near the middle of the femur, to get flaps from the tissues above the seat of the tumor. Anæsthesia will be produced by the bromide of ethyl, which I have used during this winter, in my clinical service, almost exclusively. It is an agent pleasanter than ether, more rapid in its action, more evanescent in its effect, and apparently rather less liable to cause vomiting. The amount necessary to produce profound insensibility is far less than is the case with sulphuric ether. This is the largest operation in which the bromide of ethyl has been used by me as an anæsthetic agent, and it will be interesting to note the time occupied and the amount required. Two fluid drachms are poured upon a piece of folded lint, covered by a towel, to begin with, and one drachm added at intervals, as circumstances indicate. Although this anæsthetic resembles chloroform in many physical properties, it must be administered like ether, except in much smaller quantities. The woman is now ethylized, if we may use the term, and the elastic bandage is applied from the toes to a point above the middle of the thigh. A flat rubber band, an inch and a half wide, is then used for the tourniquet, instead of Esmarch's rubber tubing, which I dislike, because it constricts the nerves and tissues too firmly. Anteroposterior flaps are made, consisting of integument and a comparatively small portion of muscular tissue, which are always preferable to thick muscular flaps. The bone is readily divided a little below the middle third, and seems somewhat less hard than normal. The elastic tourniquet is removed after the femoral artery has been secured by a carbolized catgut ligature, which is, of course, cut off close, and allowed to become absorbed. Only two other vessels require ligation. The parts are approximated by wire sutures, and a rubber drainage-tube is introduced through the outer angle of the wound. The wound will now be washed out very thoroughly with carbolized water, forced in through the openings between the sutures by means of a Davidson's

syringe. This antiseptic method, which I believe is my own, is one of the most important features in the dressing of amputations and excisions. The water which contains carbolic acid, in the proportion of one to forty, is pumped in until it gushes out between the sutures, and carries with it all clots and bone-dust that may still be between the flaps. The end of the syringe is inserted into various openings successively, until the distended cavity is thoroughly cleansed and filled with the antiseptic solution. The water is not pressed out, but a piece of lint, saturated with carbolized oil, is applied, and a firm bandage adjusted. By this means, putridity and suppuration of the wound are avoided as much as possible, for decomposing clots are prominent factors in preventing union and causing suppuration.

Let us now see how much bromide of ethyl has been used during the operation. The patient was kept under its influence thirty-three minutes, during which time ten fluid drachms of the agent were administered. The anæsthesia at times was accompanied by stertorous respiration, and it was observed that during profound insensibility the pupils were contracted, though we have generally observed dilatation at such times. Consciousness returned promptly two minutes after the towel was withdrawn from her face, and the patient almost immediately expressed her thanks that the tumor had been removed. There was some nausea exhibited. . . . . The dressing was not removed for four days, and at the end of a week the sutures were all withdrawn, as union had taken place along the entire wound, except at the angles where the drainage-tube was placed, whence there was a small amount of healthy pus escaping. There has been some surgical fever, but the patient now, after the lapse of two weeks, is almost well, and could even be discharged. There is still, however, a little point at each angle where cicatrization is not complete, and whence a small amount of pus escapes. Microscopical examination by the pathologist showed the tumor to be a giant-celled sarcoma.

Original Communications.

MIDWINTER TREATMENT OF PHTHISIS IN MINNESOTA.

Clinical Study of Thirteen Cases, with Results.

By TALBOT JONES, M.D.,

ST. PAUL, MINN.

The *New York Medical Journal* for September, 1879, contained a paper written by myself, entitled "A Plea for Cold Climates in the Treatment of Consumption," in which I endeavored to give the profession some idea of the climate of this State with special reference to its effects upon subjects with phthisis pulmonalis, and at the same time expose some of the fallacies which obtain with regard to certain southern sanitaria, especially Florida and the West India Islands. The many and favorable notices which this article provoked, together with several reviews of it in the medical press both of this country and Great Britain, has induced me to widen and extend my investigations of this subject.

In my desire to make good my statements with reference to the favorable influence the climate exerts upon many cases of phthisis, I have, since the publication of that paper, kept a record of such cases as have come under my observation, and have been careful to make the notes as full as is necessary to a clear understanding of them by the profession at large. Gentlemen can then draw their own deductions as to results of treatment. The fact must not be lost sight of that the notes were made only during winter treatment. As the winter climate of this State has been persistently misrepresented, and its hurtful effects upon phthisical subjects greatly exaggerated, I am glad thus to be able to show, by these clinical cases, its actual effects in this direction.

There can be no difference of opinion as to the favorable influence it has during the summer months. This, I believe, is now no longer disputed in any quarter. But many excellent practitioners, in different portions of the country, fear that this climate during the winter season is too severe, and that nothing but harm can result to patients who spend their winters in this State. However, the cases I herewith report will show that, far from being injurious, the winter climate of this State is positively curative or beneficial.

Case I.—Sept. 3, 1879. Miss L., aged 20 years. Residence on Rondo street, in this city. Has had several hemorrhages. Predisposition to phthisis through heredity. Two of the family have died of the disease. One sister, at this writing, under treatment of a physician here for the same malady. Weight, 105 pounds. Is employed as a sewing-girl in a crowded manufacturing department of a large dry goods house. Present here much dust and bad ventilation. She is anæmic in appearance. Appetite quite gone. Has been troubled with cough for six months, first dry and hacking; now raises more or less muco-purulent matter. Has certain dyspeptic troubles. Dyspnœa upon exertion. Night-sweats and hectic. Physical examination showed bronchial breathing over small area at apex of right lung; broncho-vesicular respiration extending from one to one and a half inches beyond this spot. Slight involvement of apex of other lung. Dulness, though not marked, upon percussion over affected portion of the lung. Pulse, 104. Temperature, 101½° at noon. I advised her to quit her present employment; to take more exercise in the open air; sleep in well-ventilated apartments.

Sept. 30th.—Much improved, appetite partially restored. The cod-liver oil I prescribed could not be taken, and finally its use had to be abandoned.

Oct. 15th.—Continued improvement; night-sweats no longer experienced; cough much less, though expectoration rather more profuse and muco-purulent. Physical examination shows a persistence of the lung lesions, with no apparent improvement. General health much improved. Weight, 109 pounds. Color, before pale, now much better.

Nov. 5th.—Improvement so marked that, against my advice, she resumed her old employment in the dry goods store.

Case II.—Dec. 20, 1879.—Mr. L., of Philadelphia; patient of Dr. Hinkle, Dr. Da Costa consulting physician. Is 34 years old, and has led a sedentary city life. Has had, at intervals, hemoptysis three different times. Weight, 153 pounds. Before coming to Minnesota, he suffered from dyspnœa upon slight exertion, as in ascending a stairway or other acclivity. A walk of a few blocks caused rapid and difficult breathing. This case I did not examine physically, and know that there is some infiltration at the apex

of the right lung only from the patient's statements. He was told so by Dr. Da Costa after examination. I was not called upon to examine this patient for the reason that he did not need medical treatment—his improvement having been steady and uniform since his arrival here.

Jan. 26, 1880.—Patient remarkably improved in every way. Cough much less than formerly. Appetite keen, and assimilation of food perfect. The dyspnœa formerly experienced in walking has grown less and less, until to-day he walked to Lake Como and back—distant from this city two and a half miles—without experiencing fatigue. Prognosis in this case very favorable. It is one of those cases which would have been benefited by almost any change of climate.

February 1st.—Has gained twelve pounds since his arrival in this city. Treatment: cod-liver oil.

Case III.—Mr. J——, residing on corner Tenth and John streets, St. Paul, aged 40. Last fall had pneumonia, through which Dr. S. D. Flagg, of this city, safely carried him. Since then he has never been entirely well, but has had cough, more or less dyspnœa upon exertion, pleuritic pains, though never hæmoptysis; night-sweats occasionally, though never profuse or exhausting. Has lost considerable flesh. Has suffered from a constant pain over the apex of the left lung. A physical examination revealed dulness and other signs of infiltration, together with broncho-vesicular respiration at apex of left lung. Right lung somewhat emphysematous, which, as a complication of phthisis, is, in my experience, unusual. Another favorable case with regard to prognosis. Treatment: cod-liver oil and inhalations of tar-water and carbolic acid. Under this treatment, together with exercise in the fresh air, Mr. J. has greatly improved. Cough diminished. The loss of flesh, which was a marked feature in this case, was arrested, and he is now in a fair way to recovery. Has gained twelve pounds in three months, and is now free from pain and dyspnœa.

That this climate does not always act thus favorably is well shown by reference to

Case IV.—Miss O——, aged eleven years, residing on Franklin street in this city; lately from Canada, more recently from Minneapolis. Dates her illness from an attack of scarlet fever, which occurred during last May—eight months ago. Then lived in Minneapolis, and treated by Dr. Dunton. Has been more or less unwell from that time till about two months since, when there appeared a sudden aggravation of all the symptoms. She then began to experience great dyspnœa upon the slightest exertion. The number of respirations increased to twenty-eight or thirty per minute. Pulse two weeks later, when I first saw her, was 103¼° F. in the afternoon, and 100½° the following morning. She now had severe and exhausting night-sweats, harassing cough, and complete loss of appetite. She soon grew so weak that it was with difficulty that she was able to walk across the room. No hereditary taint. Physical examination showed the following condition of the lungs: dulness over the entire upper portion of the right lung, and, to a less extent, below this. The respiratory murmur exaggerated on the opposite side. Moist râles heard over the entire right lung. Auscultation showed marked bronchial breathing, with loud and prolonged expiratory murmur. Bronchophony. Cracked-metal sound upon percussion. Infra-clavicular region of right side sunken in.

Jan. 23d.—Continued high fever; some delirium at night with constant headache, and pain in the abdomen. Diagnosis: miliary tuberculosis, involving brain and bowels. Pain in the bowels so severe and constant that an opiate is necessary to quiet it.

Jan. 30th.—Night-sweats not so severe. Appetite better, and the child much more comfortable. Cannot arrest the loss of flesh. She is now thin almost to emaciation. Prognosis, of course, extremely unfavorable. She will probably not live a month.

Case V.—Mr. F——, resides near Lancaster, Penn. Patient of Dr. Raybrook. Dr. Wm. Pepper, of Philadelphia, consulting physician. There is slight infiltration at apex of left lung, with broncho-vesicular respiration over the lesion. No hemorrhages. Cough never very severe. Age of patient, twenty-nine years; weight, 155 pounds. The improvement of Mr. F. has been steady and uniform since his arrival here. All the symptoms which originally gave him trouble have now disappeared. Has gained nine pounds during the last six weeks. I have reason to believe that he will return home in a few months with his health perfectly restored. Treatment: cod-liver oil.

Case VI.—Mr. W——, of St. Paul, residing on Sherberne avenue; aged 31 years; has had phthisis for several years. Most of the time has been under the care of Dr. Owens of this city. The origin of the trouble dates back several years, and is directly dependent for its causation upon post-nasal catarrh. Dr. Owens concurs in this opinion. I will remark that, although post-nasal catarrh is an extremely common disease of this climate, that this is the only case I have yet encountered which has eventuated in phthisis. The condition of Mr. W. is as follows: weight, 120 lbs.; temperature, 100½°; respirations, 27 to the minute, much increased upon exertion; no hereditary taint; has had a cough, more or less harassing, for two years; no hemorrhages at any time; has had night-sweats though these have never been very profuse.

Physical examination.—Slight dulness upon percussion at summit of right lung, with exaggerated percussion-sounds over the opposite lung; mucus and subcrepitant râles; broncho-vasicular respiration, and an increased bronchial whisper. Slight depression below right clavicle. Mr. W. spent last winter in Florida, though with no material benefit. To my mind it is a mistaken idea to suppose that a patient leaving the highlands of Minnesota, with its atmosphere remarkably free from organic matter, rich in ozone, and which is cold, tonic, and bracing, will experience relief in the lowlands of Florida, where the atmosphere, as shown by hygrometric measurements, is loaded with moisture; which receives from two sides the marine atmosphere of the gulf and ocean, and which has in many parts of the State much malaria in it. The benefit Mr. W. derived by his trip to Florida was not enough to justify his returning the present winter.

The prognosis in this case is bad. However, for the past twelve or eighteen months the patient seems to have been holding his own very well. The case is still under observation.

Particular attention is directed to the two following cases, the import of which will presently appear. The patients are two brothers from London, Ohio. A study and comparison of their cases will strongly impress one with the value of a change of climate, if made early enough, and the uselessness of the change when, as is too frequently the case, it is made too late.

Case VII.—January 28, 1880. Mr. S——, from London, Ohio. patient of Dr. Wilderson; age, 20 years; color bad; height six feet one inch; weight

only 102 lbs.; temperature, 103½°; number of respirations, thirty-five to the minute, increased upon exertion; cough at first dry and hacking, now loose, with abundant purulent expectoration; extreme emaciation; profuse night-sweats, which have greatly exhausted patient; no hemorrhage at any time. Physical examination indicates an amount of lung disorganization, which, it seems strange, should exist and yet life be maintained. There is marked dulness upon percussion over entire infra-clavicular region of left side, with bronchial respiration, bronchophony, whispering bronchophony, and increased vocal fremitus. Cracked metal resonance upon percussion. Marked sinking in below clavicle on corresponding side. More or less broncho-vesicular breathing, with dulness upon percussion over lower portion of the lung. The lung of the right side is also badly affected. There is broncho-vesicular respiration and slight dulness upon percussion at its apex. The lung of this side more or less affected till the border of the fifth rib is reached. This patient, like so many others in his condition, put off coming here until it was too late. He has been in the State but two months. It is useless to speak of the prognosis: the question is only one of the number of days or weeks which he will yet survive.

Case VIII.—January 28, 1880. Brother of the preceding. It is fair to assume that they both have, to an equal degree, a predisposition to phthisis through heredity. A predisposition to the disease is undoubted, since already one brother has died of consumption, and a sister, at present in this State, also has it. Upon examination there was present more or less infiltration at the apex of the left lung, with slight dulness upon percussion and broncho-vesicular respiration. Pulse, 93; respirations, 23 to the minute; weight, 155 lbs.; color good; temperature normal; more or less cough of a dry, hacking kind; no night-sweats. This gentleman, unlike his brother, early took advantage of a change of climate—coming to Minnesota some eighteen months ago. He tells me that in the year and a half he has been in the State he has gained twenty pounds, and that his general health has very much improved. I would scarcely be afraid to predict for him a perfect cure, provided he remains long enough. He formerly experienced considerable dyspnœa upon exertion, but this has now disappeared. The results in these two cases are very suggestive. The one early took advantage of a change of climate, as said before; the other did not. The one has well-grounded hopes that his life may be indefinitely prolonged; the other will probably not live longer than one or two months. These are likewise instructive cases to those of our profession who are sceptical about improvement being effected by change of climate.

Case IX.—September 22, 1879. Mr. B——, of Jersey City, N. J., aged 27 years; color bad; came to St. Paul for what he supposed to be dyspeptic troubles. Weight, 117 lbs.; temperature, 99½° F.; number of respirations, 23 per minute, much increased upon exertion. Has had more or less cough since an attack of pneumonia, eighteen months ago. Has not been stout since then. Family history good; father and mother still living and well. Since his pneumonia has lost flesh slowly but steadily. Slight night-sweats at irregular intervals. Almost total loss of appetite. Two hemorrhages during the past six months.

On examination, I found slight dulness upon percussion at apex of left lung, increase of vocal resonance, and exaggerated bronchial whisper; broncho-vesicular respiration over circumscribed spot. No involvement of opposite lung. Advised the use of cod-liver oil, and insisted on his being in the open air all the time possible. At my suggestion, he went to White Bear Lake, near this city, where he could be in the fresh air almost constantly.

November 23d. Patient just returned from the lake, having been absent two months. Scarcely recognized as the same person. Cheeks now rosy. Told me he had gained 20 lbs. during his stay at the lake. Appetite fully restored; no longer has night-sweats.

His improvement so marked that he declared it as his intention to go into business in this city, and to make it his future home.

Case X.—Mrs. G——, from Michigan, aged 20 years, weight, 101 lbs. This case very much like the preceding one. The infiltration is circumscribed, but in the apex of the left lung. Temperature normal; pulse 90. Has had more or less cough, first dry, but now with some muco-purulent expectoration. Present illness due to pneumonia contracted three years ago. No history of hemorrhages. None of her family have had phthisis. Physical examination reveals slight infiltration at summit of left lung, with broncho-vesicular breathing, though this is not marked; feeble or jerking inspiration; expiration lengthened; slight dulness upon percussion; few moist râles. The lesion being slight, the prognosis in this case is favorable. It is one that would have improved by almost any change of climate. Since her stay in St. Paul (eight months), she has gained 9 lbs., now weighing 110 lbs. General health much improved; cough has almost disappeared.

This case was treated by Dr. A. J. Stone, of this city, through whose courtesy I was enabled to examine, and now to report it.

Case XI.—Mr. M——, merchant, of this city, formerly of Auburn, N. Y., aged 32. No predisposition to phthisis through heredity. His troubles date back three years. Weight, 145 lbs.; color at present, good. Suffers from post-nasal catarrh; respirations, 20 per minute; temperature normal. Only an occasional night-sweat, and then but slight; never had pneumonia; no history of hæmoptysis. Examination reveals slight infiltration at upper lobe of right lung, the spot not being larger than a silver dollar. Slight dulness upon percussion over this spot; diminished respiratory murmur, mucous râles, with a "crackling" sound heard when ear placed over the lesion. The patient was in Florida two winters ago, but did not improve sufficiently to justify him in returning.

Remained in St. Paul last winter and this. The patient is slowly regaining his strength, having gained 20 lbs. in as many months. However, there is a persistence of the infiltration, with no apparent improvement. Prognosis in this case, good. Treatment: cod-liver oil and inhalations.

Case XII.—February 3, 1880. Mrs. D——, of Dubuque, Iowa, patient of Dr. Jno. S. Lewis, of that city; married; 34 years old. Predisposition to phthisis through heredity. Patient considerably emaciated; weight, 96 lbs.; temperature, 102½° noon, 100½° morning; color bad. Persistent and harassing cough, with profuse muco-purulent expectoration. Night-sweats and more or less hectic. Never had pneumonia. Has had several hemorrhages during the past month while under my treatment. Physical examination: hollow, cavernous breathing when ear placed over summit of left lung; heard also over scapula. This murmur heard only in expiration.

Gurgling or bubbling sounds, cavernous voice. Cracked-metal sound upon percussion; dulness upon percussion over the lesion; plouritic pains over the chest and under the scapula. This, in connection with fever present, indicates the progress of the disease. Cod-liver oil could not be taken by this lady, owing to intolerance of the stomach. Prognosis bad. I doubt if the onward progress of the disease can be arrested.

Case XIII.—January 23, 1880. The following is a case which occurred in the practice of another physician of this city, who has kindly given me the data: Mr. L——, a railroad official, residing in this city, had pneumonia one year ago, and has never been entirely well since. More or less cough, which is dry and annoying. Age, 37; pulse, 93 per minute; temperature normal; respirations, 20 per minute. No hereditary taint. Since his sickness has lost considerable flesh; appetite bad, and he is troubled with what he supposes to be dyspepsia. Has had a few night-sweats, though these have never been profuse or exhausting. Weight, 121 lbs.

Physical examination shows a small amount of infiltration in the upper portion of the left lung. No dulness upon percussion over this region. Expiratory murmur somewhat lengthened. Few moist râles.

The injury to the pulmonary tissue being slight, the prognosis in this case is favorable. His physician advised a trip to Europe.

I place these cases, without comment, before the profession, and allow them to draw their own deductions as to results. I need scarcely say that they are not selected ones. Every case has been reported which has been seen by me in the time specified, and none have been withheld from publication on account of being unfavorable cases for a report. This is too serious a subject to be treated of in any such spirit of bias or prejudice.

That which is desirable in the study of this subject, to learn, and which it is of the utmost importance to know, is the actual effects of cold climates and warm upon phthisis; and, having ascertained this, we can then exercise a wise discrimination in the selection of a climate which will be best adapted to each individual case.

OSSIFICATION OF THE CILIARY BODY AND CHOROID.

By C. J. LUNDY, M.D.,

PROFESSOR OF CLINICAL DISEASES OF THE EYE, AND OF DISEASES OF THE EAR AND THROAT, IN THE MICHIGAN COLLEGE OF MEDICINE.

The development of true osseous tissue within the human eye has been occasionally noted, and yet it is sufficiently rare to warrant a few remarks upon a case which recently came under my observation, and which presented some peculiarities that had hitherto been observed only in a single instance.

It was until recently doubted by many, and is probably still doubted by a few, that true osseous tissue could be developed within the eyeball; but the question can no longer be disputed. It may be considered, then, as a settled fact that ossification may and does take place within the eye, and that this ossification is the product of a pathological process. The study of those products which are the result of tissue-metamorphosis deserves the attention of the special and general surgeon; and to some it may be interesting to know in what tissue or tissues, and under what circumstances, the ossific metamorphosis occurs. By pathologists it is pretty generally conceded that connective tissue, whether it is a natural constituent of a part or a pathological product, may be metamorphosed into osseous tissue during a plastic inflammation; and when bone is developed as a heterologous tissue, it probably takes its origin in this manner.

In speaking of the connective-tissue group (bone, cartilage, connective substance, etc.) and its behavior under pathological conditions, Frey says: "Almost every member of the group of connective tissues may be replaced by nearly any other, firstly by immediate metamorphosis, then again more particularly by reconstruction from the offspring of the original tissue."

Those cases of bony development within the eye which have been heretofore reported, have, with a *very few* exceptions, been cases in which the ossification took place within the choroid, or in inflammatory exudates from the choroid. During a pathological process true bone is likely to be developed only in connective tissue abundantly supplied with capillaries; and as the choroid has a richer supply of capillaries than any other portion of the human economy, it is naturally a favorite site for pathological osseous development. In chronic plastic inflammation of the choroid, connective tissue is found to be a constituent of the inflammatory exudation, and in rare instances this is developed into bone. It is probable, also, that bone is sometimes developed in the chorio capillaries of the choroid in a similar manner.

In an able article written a few years since, Prof. Knapp stated that ossification of the ciliary body, crystalline lens, or iris had never been observed, and expressed a doubt that ossification could take place in either of these parts. Since the publication of Professor Knapp's paper, at least two cases of ossified lens have been observed. Dr. Keyser, of Philadelphia, has reported one case in which the crystalline lens was entirely replaced by bone, and the microscopic examination demonstrated that it was true osseous tissue. Since the report of Dr. Keyser's case, another has been observed by Dr. Voorhies, of Memphis, and the microscopic examination in this instance showed that the lens was transformed into true bone. In Haynes Walton's "Treatise on Diseases of the Eye" (1875), the author states that an ossified lens was examined for him by Mr. Queckett, of the Royal College of Surgeons. The same author also states that "the whole of the ciliary body has been found ossified in an eye that had been atrophied from the pressure of a cancerous tumor." Contrary to our expectations, and contrary to our opinions regarding the circumstances under which ossification occurs, and contrary to the prediction of so able a man as Prof. Knapp, we see that ossification may take place in other parts of the eye than the choroid. Even the crystalline lens, a tissue entirely devoid of blood-vessels in the normal condition, has been found ossified in at least three cases. In this connection a question which would naturally present itself is, Whence did the plastic material come which supplied the elements for the ossific metamorphosis of the crystalline lens? I do not think it will be maintained that the plastic material was received from the choroid proper. To me it seems more probable that the ciliary body, whose circulation is largely concerned in carrying on the nutrition of the anterior portion of the eye, is the part which would be most likely to furnish the plastic elements for osseous development within the lens-capsule. Be that as it may, I shall not attempt to discuss the question further, and it has been in-

introduced here only for the purpose of showing that ossification may and does take place at other points than the choroid; and also to point out the strong probability that the choroid does not, in *all* cases, furnish the plastic matter from which bone is developed within the eye.

It is to be regretted that Haynes Walton, in referring to the case already quoted, has given nothing beyond the fact that the whole of the ciliary body had been found ossified. In the case which I am about to report, however, I have taken pains to have the specimen examined by a gentleman who is not only an expert microscopist, but who is also familiar with histology and pathology. I refer to Prof. Chas. H. Stowell, M.D., of the physiological laboratory of the University of Michigan. Dr. Stowell had the kindness to "mount" two microscope sections for me, which are represented in Fig. 2.

The history of the case is briefly as follows: Anna K ——, æt. 34, unmarried, of good constitution and fair general health, had small-pox when she was seven years of age and as a result of variolous pustules on the cornea she became blind in the left eye. As a result of the ulceration the cornea was perforated, prolapse of the iris occurred, and the inflammation extended to the choroid, subsequently implicating the ciliary body, thus involving the whole uveal tract. After a time the inflammatory symptoms abated, leaving the eye perfectly sightless, and the ball slightly atrophied. Seven years ago she began to wear an artificial eye over the atrophied bulb, and has continued to wear it most of the time since. After wearing the artificial eye for three or four years, the blind eye began to be irritable and painful at times, and for two years past she has been unable to wear the artificial eye constantly, on account of the discomfort it produced. For a year or more she has suffered from attacks of sympathetic irritation in the fellow eye, such as photophobia, lachrymation, accommodative asthenopia, blurring of vision, etc. These attacks were aggravated by any persistent attempts to wear the artificial eye, or by reading, sewing, etc. As the blind eye was irritable and painful, as the sympathetic trouble was increasing in severity, and as the case was liable to terminate in sympathetic ophthalmia, which would be likely to prove fatal to the sight of the fellow eye, it was deemed advisable to enucleate the atrophied bulb, and thus insure the patient against the risk of total blindness. It is often advisable to consider the cosmetic effect (particularly if the patient is a female) before deciding to enucleate an eye, and where an operation is imperatively demanded, the operation of neurotomy optico-ciliaris, as I have performed it, may often be substituted for enucleation. For obvious reasons, however, the cosmetic effect was not taken into consideration in this instance.

On July 17th I enucleated the eye. After it was removed it gave to the touch a sensation of rigidity such as we get in eyes containing bone or calcareous matter; and this hard resistant feeling was so marked in the anterior portion of the ball, that the presence of bone was at once suspected.

The diameters of the eye were shorter than those of the normal eye, as the following measurements will show: Antero-posterior diameter, 21 mm.; transverse diameter, 22 mm., and vertical diameter, 22 mm. The short antero-posterior diameter of the ball was largely due to a flattening of the cornea, which had lost all appearance of corneal tissue. The eye was placed in dilute alcohol, and was allowed to remain two weeks before being opened.

The eye was opened by an equatorial section, which divided the ball into an anterior and a posterior half, as shown in Fig. 1.

The retina was detached, as is usually the case when bone is developed in the choroid. In the pos-

FIG 1.

terior half of the globe (Fig. 1, at A,) a thin, compact plate of bone extended forward from the entrance of the optic nerve to the ora serrata. This plate of bone had no connection with that in the anterior portion of the eye (Fig. 1, at B) and no process of bone extended transversely inward to the centre of the eye, as has sometimes been observed. This thin plate of bone seemed to have been developed between the retina and the choroid, which led me to suppose that it originated in an inflammatory exudate which was poured out from the choroid during the long-continued inflammation of that portion of the uveal tract.

The chief point of interest, however, is the osseous development in the anterior portion of the eyeball (Fig. 1, at B). The ciliary body was found to be almost completely ossified, and its site occupied by a bony ring, which was not completely ossified at one point. In the centre of this osseous ring the crystalline lens was found embedded, and, after its removal, the remains of the iris were visible, and in the diagram they present a dark appearance. The bone occupying the site of the ciliary body was very firm and dense, and varied in thickness from 4 mm. to 0.5 mm. Its width varied at different points, but the diagram (B, Fig. 1), which is only a trifle larger than the specimen, illustrates this tolerably well.

From the microscopic sections prepared for me by Professor Stowell, I had drawings executed (Fig. 2) by Dr. Willard Chaney, assistant to the chairs of physiology and laryngology in the Michigan College of Medicine. These cuts illustrate the appearance of the sections when viewed through the microscope:

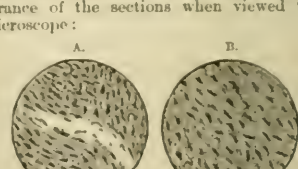

FIG. 2.

Figure 2, at "A," shows the appearance of the section from bone in the ciliary body, and at "B" the appearance of the section from bone in the choroid.

In both sections the lacunæ and canaliculi show very nicely. One point which is especially deserving of notice, in the section from bone in the ciliary body, is the presence of a Haversian canal, which in the diagram (Fig. 2, at A) may be seen as a

slightly curved line passing nearly through its centre. The presence of Haversian canals, in small irregular pieces of bone, which are of pathological origin, is quite rare. Although the absence of Haversian canals does not disprove the presence of true bone, yet the presence of these canals is a very positive proof of true ossification.

After making the examination and mounting the two microscopic sections for me, Professor Stowell sent me the following communication:

"The specimen marked 'Bone from Choroid' was taken from the thin plate of bone which lines, or rests upon, the choroid. Here you see the lacunæ, canaliculi, and even Haversian canals. The specimen marked 'Bone from Ciliary Body' was taken from the bony ring which corresponds to the ciliary body. Here you have *bone* in all its beauty. Notice what large lacunæ, and even how nicely the canaliculi show. The Haversian canals are not even wanting here.

"The bone was clipped from the 'ring' with scissors, then ground between bones, and mounted in hard Canada balsam; the object being to retain *air* in the lacunæ and canaliculi; and thus having the highly refractile balsam on both sides, the air looks dark—nearly black.

"I consider this one of the choicest and most rare specimens I have ever seen. Its origin is certainly strange to me."

As to the rarity of the specimen there can be no doubt, for, so far as I am aware, it is the first instance in which ossification of the ciliary body has been properly demonstrated. Stellwag states that osseous scales have been found in the ciliary body in cases where chronic irido-choroiditis had existed. Where an irido-choroiditis exists for any length of time the ciliary body must, of necessity, be implicated; and in the case of my patient there is no doubt that a chronic inflammation of the whole uveal tract, iris, ciliary body and choroid, existed for a long time. What influence the wearing of the artificial eye may have exerted over the process of ossification, by helping to keep up a chronic cyclitis, is an interesting question, but one whose solution is impossible.

52 Lafayette Avenue, Detroit.

ANATOMICAL ANOMALIES.

By Dr. ELLIOTT COUES, U.S.A.

I desire to place on record the following very unusual arrangement of the branches of the subclavian arteries, discovered by Mr. Frank Baker, Prosector to the Chair of Anatomy in the National Medical College at Washington. The subject was an adult male, colored. The subclavians themselves were normal.

On the right side.—Thyroid axis small, undivided for an inch or more, then dividing into transversalis colli, inferior thyroid, and ascending cervical. Transversalis colli very small and lost in the scalenus medius and levator anguliæ scapulæ, instead of continuing down the scapula or posterior scapular. Posterior scapular given off from the first portion of the subclavian, of large size, passing directly to the posterior superior angle of the scapula, and thence continuing down the vertebral border of that bone.

Suprascapular of great size given off from the internal mammary, one and a half inches from the origin of that artery, escaping from the thorax by rising behind the first rib; thence proceeding straight to the scapula, behind the subclavius muscle, crossing the subclavian artery in the third portion of the course of the latter, and gaining the suprascapular notch by passing over the transverse ligament.

Internal mammary normal in its origin and course, but giving off the suprascapular, as just described, and also giving off a second or supernumerary inferior thyroid artery, additional to the weak inferior thyroid already noted as a branch of the thyroid axis, thus transforming itself into a sort of "mammary axis."*

Vetebral and superior intercostal as usual

Thus, the right subclavian had *five* branches instead of four, the additional branch being the posterior scapular. The arrangement otherwise peculiar in the following respects: *a*, presence of a supernumerary inferior thyroid, arising from the mammary; *b*, transversalis colli not continued as posterior scapular, which was an independent branch of the subclavian; c, origin of suprascapular from the mammary.

On the left side.—Condition of the weak thyroid axis as on the right side.

Posterior scapular arising from second portion of the subclavian.

Suprascapular arising from the subclavian at onter border of first rib; thus, almost from the axillary, and very different from the same artery on the right side and passing under the transverse ligament with the nerve.

A small, anomalous artery, soon spent on the scalenus medius and longer colli, arising independently from the first portion of the subclavian.

Vertebral, superior intercostal, and internal mammary normal.

There were thus *seven* branches of the left subclavian, the three abnormal ones being the posterior scapular, suprascapular, and the anomalous artery just mentioned.

To recapitulate the chief points:

1. Both posterior scapulars from the subclavians, with no connection with the transversalis colli.

2. Right suprascapular arising in the thorax from the internal mammary (nnknown before?).

3. Duplicate inferior thyroids on the right side; the supernumerary one from internal mammary.

4. Anomalous artery from first portion of left subclavian.

5. Right subclavian with five branches; the left with seven.

Washington, D.C., February 11, 1880.

Compulsory Examination for Color-blindness.—The Secretary of the Treasury has issued an order to the local steamboat inspectors directing them not to give new licenses to pilots, or renew old ones without a preliminary examination for color-blindness. The examinations are to be made by the surgeons of the United States Marine Hospital Service, and are free of charge.

* Mr. Baker suggests a different view: to regard what I have called "thyroid axis" as only the transversalis colli, giving off ascending cervical and tracheal branches; what I have called the supernumerary inferior thyroid as the true artery of that name, though coming off from a mammary. This would give, as hinted in the text, a sort of "mammary axis," dividing into inferior thyroid, supra capular, and mammary proper.

I may add that, in dissecting the right axilla, the subscapular was found nearly as large as the brachial, and that from it arose two long thoracics—the posterior circumflex and the superior profunda of the arm.

THE
SALICYLATE OF POTASH IN ACUTE RHEUMATISM AND DYSPEPSIA.

By M. DONNELLY, M.D.,

NEW YORK.

The alkaline treatment in acute rheumatism has always impressed me with the idea that it was the most thorough and scientific course, and the one best calculated to neutralize the acid poison in the blood causing that painful disease; and when the salicylate of soda was added to our therapeutics, I found it of great assistance in limiting, or cutting short, attacks of acute rheumatism.

But the salicylate of soda, a neutral salt, never seemed sufficiently alkaline to correct the acidity of the blood, and so long as the blood remained acid, there was danger of the heart becoming involved; and this to my mind explains the frequency of cardiac disease under the salicylate of soda treatment. This theory has been proven by some experiments reported in the *Lancet*, Sept. 20, 1870, by Drs. Findlay and Lucas, who found that the salicylate treatment gave the most prompt relief, but there was an increase of endocardial and pericardial disease over the simple alkaline course.

The desire to combine the rapidity of action of the salicylic acid with the safer alkaline course, prompted me to investigate the subject, and *the salicylate of potash* is the result of my labors.

The alkali I have found most prompt in neutralizing the acidity of the blood is the bicarbonate of potash, and the thought occurred to me that this salt, from its ready solubility, might be united with the salicylic acid, and thereby obtain a *thoroughly alkaline salicylate*. Three parts of salicylic acid, and two parts of bicarbonate of potash in water, formed a neutral solution: but I found that the potash could be increased to the proportions of *two* of the alkali to *one* of the acid; say, twenty grains of the bicarbonate of potash to ten grains of the salicylic acid, in one drachm of water; and this solution evaporated to dryness left a strongly alkaline salt—the salicylate of potash—extremely soluble in water, and of a sweetish taste.

For several months I have prescribed the salicylate of potash with the greatest benefit in two diseases: acute rheumatism and dyspepsia.

The large doses of salicylic acid, or the salicylate of soda, required to act in acute rheumatism, is one of the greatest objections to their use, especially when any cardiac disease exists or is feared. In employing the salicylate of potash, large doses of the acid are not required; from eight to twelve grains of the acid to double that quantity of potash seems quite sufficient—the following formula being the one I have most frequently prescribed:

℞ Acid. salicylic..... ℈ iij.
Potass. bicarb..... ℈ vj.
Aquæ ..... ℥ ij.
M. S.—A teaspoonful every three hours.

The rapidity of action of this combination is remarkable. Its absorption seems to be immediate; the patient will speak of the speedy relief he experiences; the blood is restored to its natural alkalinity, as seen by the diminished acidity of the perspiration and urine; the brick-dust sediment (urates) in the latter disappears, the pain and swelling of the joints soon subside, and the metastatic character of the disease is lost. Judging from the effects in a dozen cases in which this treatment has been employed, it is no over-estimate to say that the salicylate of potash seems as thoroughly abortive of acute rheumatism as quinine is of intermittent fever.

The salicylate of potash is continued as long as pain and swelling remain, and then iodide of potash is given for a short time, but a most essential part of the treatment is yet to be mentioned.

The blood not only should be rendered alkaline, but also restored to its normal condition, by the administration of an alkaline form of iron; and the best for this purpose is the tartrate of iron and potash. The following is my mode of prescribing it:

℞ Ferri et potassii tartras . . ℈ iij.
Aqua fervens .. . . ℥ iij.
Fiat solutio, adde
Glycerini ..... ℥ vj.
M. S.—A teaspoonful in two ounces of water three times a day, two hours after meals.

No relapses and no heart disease have followed in the cases treated in this way.

Adopting the theory of Murchison, that gout, rheumatism, and derangements of digestion arise mainly from "functional diseases of the liver," I find it good practice to commence the salicylate treatment by a brisk mercurial cathartic.

The well-known quality or power in salicylic acid, of preventing fermentation and controlling noxious gases, first led me to try this drug in dyspepsia, and I found it very promptly relieved flatulence and eructations of gases from the stomach; and not only this, but it was also very soon apparent that as a stomach tonic it was superior to quinine or barks.

The powder was first used, then the salicylate of soda, and last the salicylate of potash—the latter proving more beneficial than either of the other forms, which may be attributed in a great measure to the alkali acting on the biliary secretion, while the salicylate, combined with tincture of nux vomica, makes an excellent stomach tonic. A favorite formula of mine for dyspepsia is:

℞ Acid. salicylic.,
Potassa bicarb ..... ää ℈ ij.
Aqua,
Syr. cort. aur..... ää ℥ vj.
Tr. nucis vom..... ℥ ij.
M. S.—A teaspoonful three times a day.

This remedy is administered in a wineglass of water, half an hour before meals, until the appetite improves; then is taken soon after eating, for the purpose of stimulating the digestive organs, especially as Balfe has demonstrated that the alkalies have a more decided action during the process of digestion than when the stomach is empty.

Whenever torpidity of the liver and its sequence, constipation, are found as a cause of dyspepsia, I prefer to use the twentieth of a grain of strychnine with one and a half to three grains of aloes and myrrh.

In conclusion, I submit the salicylate of potash to the profession, hoping it will prove as safe and speedy a remedy in other hands as it has been in mine, in the cure of acute rheumatism and dyspepsia.

354 WEST THIRTIETH STREET.

DR. E. M. NELSON has been appointed editor of the *St. Louis Courier of Medicine*. He is an experienced and energetic journalist.

Progress of Medical Science.

Hare-lip. — In a very elaborate paper on this subject, Dr. W. I. Wheeler, of Dublin, enters into the minutiæ of this deformity, and relates a few striking cases, selected from a large number that have come under his observation. All of these cases were successfully operated on, the distorted parts being restored to their normal positions. With respect to the proper time for operation, Dr. Wheeler claims that no absolute rule can be laid down. When feeding is seriously interfered with, it may be necessary to correct the deformity very soon after birth, while again the patient may not be possessed of sufficient vital force to withstand so severe a shock until months, or even years, have passed. When, however, the surgeon is able to make a choice, Mr. Wheeler would choose from *three to six weeks after birth, and certainly within three months.* There are several results to be looked for from the operation, the most important being the closure of the fissure. It would seem equally essential, however, that the prælabial curve should be restored, the unsightly notch prevented, the fossa labialis formed, and the nose, whether distorted on one or both sides, restored to its proper position; and all these can, in the majority of cases, be attained by a proper exercise of surgical artistic skill. The treatment of the protrusion of the intermaxillary bone is fully discussed in the paper, and the conclusion arrived at that it should not be removed. In almost every case it can be bent back into position, and held there by interosseous sutures, the gums being joined over it by the interrupted suture. Dr. Wheeler believes that the hare-lip pin affords the best means for avoiding the notch, elevating the nose when depressed, and holding the parts evenly together. He believes, further, that no instrument or special bandage devised for supporting the cheeks will ever supersede plaster or give the same even support. In addition to the narrow strips ordinarily employed, great advantage will be derived from a large strap passing under the chin to the malar bones, the soft parts being pushed forward towards the mouth before its final adjustment. To prevent hemorrhage from the coronary arteries he uses strong spring-compressors, which facilitate the operation by affording more room for the operation, steadying the muscles, and rendering the cut edges much drier when about to be joined. He uses the scissors for refreshing the edges in preference to the knife, and claims that much advantage is derived from the addition of a sheath on the under blade. By means of this modification the operator can accurately gauge the amount of tissue cut, and thus sever it in one stroke. the solidity of the under-blade giving support to the lip. The addition of this sheath gives all the advantages claimed for the bistoury, and removes the objection to the scissors.—*The Dublin Journal of Medical Science*, January, 1880.

Laryngeal Hemorrhage.—Dr. J. H. Hartman, of Baltimore, reports the following case: The patient, a member of a singing society, had, on the evening in question, attended a rehearsal, being then in perfect health. About an hour after his return home he experienced a choking feeling and expectorated two or three ounces of pure bright-red blood; this was controlled by the free use of ice. The next morning, soon after rising, he had another hemorrhage, but this time the ice produced no effect. On examination no pulmonary or heart trouble could be ascertained. On inspecting the larynx it was found that the hemorrhage was caused by the rupture of a capillary vessel about the middle of the left ventricular band. The flow of blood was checked by a strong solution of ferric alum with glycerine and water, each ʒ ss.—*Reprint from St. Louis Medical and Surgical Journal*, December, 1879.

The Accidents which have been Observed after Thoracentesis by Aspiration Practised for the Removal of Pleuritic Effusion.—Dr. N. P. Dandridge, of Cincinnati, sums up an article on the above subject as follows: The operation should not be considered as a trivial one; the conditions and surroundings of the patient, in reference to the most efficient means for combating any unpleasant consequences, should be taken into consideration. The operation should only be undertaken when complete repose and rest can be secured afterward, as fatal symptoms have developed in half an hour or more after aspiration. The following accidents may occur: syncope, fatal or transient, due either to reflex action, or to the paralyzing influence on the heart-walls of the sudden removal of the pressure of the pleuritic fluid; convulsions, either reflex, or due to minute emboli in the cerebral vessels; pulmonary congestion and œdema suddenly developed, either with or without the rapid accumulation of a serous exudation to the bronchial tubes thus producing asphyxia; embolic obstruction of the pulmonary artery in the sound lungs; embolic processes in different organs, of varying degrees of severity and having their origin in clots previously formed in the pulmonary veins of the compressed lungs. When these last occur about the time of, or soon after the operation, they may have been excited by it; if they develop days afterward they must be held as incident to the original trouble, and no way connected with the operative measures undertaken. He does not consider that there is conclusive evidence to show that the transformation of a serous into a purulent effusion is due to the operation. Nor does he believe that serious accidents have occurred from wounding the lung.—*The Cincinnati Lancet and Clinic*, January 3, 1880.

On the Treatment of Night-Sweating in Phthisis—Jaborandi and Pilocarpine.—Dr. Murrell publishes the results of treatment in thirty-three cases of sweating, in which either jaborandi or pilocarpine was administered. Thirty patients were affected with phthisis; seventeen cases were given pilocarpine, generally the nitrate, but occasionally the hydrochlorate. The dose was usually one-twentieth of a grain; at first it was administered in solution in water, but latterly in the form of pill, with sugar of milk. The drug was given three or four times a day. In night-sweating one dose at bedtime will suffice, unless the sweating is profuse, when it is best to give three pills during the night. He never gives the drug hypodermically. Pilocarpine acts slowly; it does not over-dry the skin, but leaves it moist. On account of its tastelessness it can be readily administered to children. Jaborandi was given in sixteen cases; two had rickets, one emphysema and bronchitis, while the remainder were affected with phthisis. The doses varied from one to twenty minims every three or four hours. In a case of sweating accompanied by flushings, the tincture of jaborandi, in minim doses every three hours, checked the former in one week, but the flushing remained. On the other hand, in two cases in which there were flushings but no sweat-

ing, relief was obtained by the use of tincture of jaborandi, in five-minim doses every four hours. Phthisical patients stated that the drug "did the cough good," "brought up the phlegm," and "eased the breathing." It is therefore useful as an expectorant.—*The Practitioner*, December, 1879.

A Contribution to the Therapeution of Starch-Digestion.—Dr. Roberts, of Manchester, England, gives the results of his investigations on the subject of the digestion of starch. He says that in infants under three or four months of age saliva has a feeble diastatic power; further he has ascertained that the pancreas of sucking calves does not possess any diastatic power, and that it is fair to presume that the pancreas of the infant at the breast is in the same condition. For this reason farinaceous food cannot be digested by young infants, unless some artificial means be employed. Malt-extracts being infusions of malt concentrated to the consistency of syrup or molasses, by evaporation (containing about seventy per cent. of maltose, which is of no more value as food than an equal amount of syrup), the diastase exists only in small quantity. As to malt-infusion, it possesses powerful diastatic properties. It is made as follows: three ounces of crushed malt are very thoroughly mixed in a vessel containing a half-pint of cold water; the mixture is allowed to remain from twelve to fifteen hours, and then passed through filtering paper until it comes through perfectly bright. It is rich in diastase, and contains maltose in considerable quantity. As it is liable to fermentation, it should be freshly prepared each day, or it may be preserved by adding a few drops of chloroform to the infusion, and keeping it well corked. He thinks that the malt preparation will prove of more service if taken with the food than after the meal, as, by so doing, it will become thoroughly mixed with the food. An excellent way of administering malt-infusion is by adding one tablespoonful to half a pint of gruel. In conclusion, he speaks of the liquor pancreaticus, made by infusing one part of fresh pancreas with seven parts of water; this was found to possess twenty times the diastatic power of the malt-infusion alluded to.—*The Practitioner*, December, 1879.

The Diseases of Blood-vessels of the Ovary in Relation to the Genesis of Ovarian Cysts.—Dr. Noeggerath does not believe that the development of the cystoma adeno-glandulare is due to an angiomatous genesis of ovarian cysts, the objection being that it is necessary to assume that it is developed from tissue which, in its embryonic state, belongs to a non-epithelial stratum. He describes the bodies sometimes found in the ovaries as presenting the shape of leaves, elliptical, ivy-, or kidney-shaped, some having a stalk of denser tissue than the mass itself. The body consists of a homogeneous mass made up of minute fibres, composed of granular matter. The stalk spoken of above was found to be a blood-vessel, gradually passing into the leaf-shaped body, this latter structure being more hyaline. In examining the ovaries of women beyond the climacteric period, he found blood-vessels undergoing hyaline degeneration. A peculiar feature is, that the vessel is not affected by carmine, rosaniline, or hematoxiline, while the surrounding tissues are deeply stained. The coats of the vessels are enlarged, and the lumen very much encroached upon. The intima, or the adventitia, in the beginning of the process, begin to look sclematous, the single fibres of connective tissue becoming indistinct, and finally appearing like a number of finely split up white elastic tissue fibrils which have been glued together. The nuclei soon began to grow thinner and shorter, remaining thicker in the centre and thicker at the poles, assuming shapes occasionally seen in myxomatous tissue. The gradual giving way of the nuclei is the cause of the resistance to staining, although eosine with hematoxyline causes the altered vessels to assume a faint, rosy, or yellowish rosy color. As to the changes in the vessels, loops of vessels can be seen merging into bodies which show no markings and form but one homogeneous mass; they then look like the corpus albicans between the third and fourth month after gestation. Both veins and arteries may undergo this process, and he therefore believes that a great many bodies heretofore described as corpora albicantia and lutea, are nothing but degenerated blood-vessels. Another form of degeneration occurs in the smaller arteries, of a twofold character: first, a hyaline degeneration of the connective-tissue portion of the intima, and of the fibres dispersed between the single rows of muscle-cells; second, a growth of the cellular elements of the media, so that lumen becomes almost entirely obliterated. Groups of vessels lying together are often affected, and closely resemble the corpus luteum of pregnancy. The principal difference in the two bodies is that while the cellular elements of the corpus luteum give way before the connective-tissue portion interposed between the cells, and become more solid, the other body, by atrophy, loses its fibrous elements, owing to the growth of single cells. In the first there is an irregular cavity in the centre, containing broken-up cells which are glued together in a shapeless mass. Gradually all the cells in the group of disorganized vessels become separated, softened, and are dissolved; by exosmosis, the serous portion is increased, and a small cyst results, the walls of which consist largely of normal ovarian tissue. The writer then describes other changes which take place, resulting in the formation of cystic cavities.—*Reprint from Am. Jour. of Obstet.*, January, 1880.

The New Anæsthetic—The Bromide of Ethyl.—Dr. R. J. Levis gives the results of his observations as to the anæsthetic properties of this drug. It is characterized by rapidity of action and quick recovery from its effects. It does not influence the circulation to any marked extent, nor is there the same danger from cerebral anæmia and fatal syncope as is seen when chloroform is used. In its effects on the respiration, bromide of ethyl resembles ether more than chloroform, producing only ordinary anæsthetic sleep. Nausea and vomiting are less frequent than with other anæsthetics. Its odor resembles somewhat that of chloroform, although it is less agreeable. It also possesses an advantage over chloroform in being entirely eliminated through the lungs. There is less tendency to struggle and to general excitement, when the bromide is used, than when the other anæsthetics mentioned are employed. Anæsthesia is generally produced by this drug in from two to three minutes, and the quantity necessary to produce this result is from one to eleven drachms.—*Reprint from Phila. Med. Times*, January 17, 1880.

Oil of Eucalyptus an Innocuous Substitute for Carbolic Acid.—Schulz, of Bonn, has found that oleum eucalypti is devoid of all toxic action. This oil appears to combine the various advantages of carbolic acid without sharing its dangerous properties. It was found to have powerful antiseptic quali-

ties; was readily soluble in alcohol and oil, and mixed well with paraffine; besides, it had an agreeable odor. Lint, gauze, etc., prepared with the oil, make convenient and serviceable antiseptic dressings. It is also suitable for the spray and irrigation.—*Centralbl. für Chir.*, No. 4, 1880.

Spontaneous Osteomyelitis of the Long Bones.—In a paper on this subject, read before the Rock River Medical Society, of Wisconsin, Dr. Senn, of Milwaukee, formulates the following conclusions, after consideration of his own cases and those found in the literature of the subject:

Spontaneous osteomyelitis is an infectious disease.

It is most prevalent in damp, changeable climates, and during the winter and spring months.

It affects, by preference, individuals during the period of growth and development of bone.

Traumatism and other agencies, which produce a retardation or arrest of circulation in the vessels of the marrow, act only as determining causes.

Its primary seat is usually in the marrow of the cancellated tissue, in close proximity to the epiphyseal cartilages.

Joint affections are frequent and prominent complications of this disease.

Thrombosis and inflammation of the veins of the marrow-bone, periosteum and soft parts, are of frequent occurrence, and are the direct causes of pyæmia.

Swelling is absent for the first few days, but, when it does occur, becomes rapidly diffuse, and is attended by œdema and enlargement of the superficial veins.

Fluctuation is diffuse, so far as its existence can be ascertained.

A constant high temperature and typhoid symptoms indicate the gravest type of the disease.

Death may result from the intensity of the primary infection, but is usually produced by some complication.

Early removal of the products of inflammation, under strictest antiseptic precautions and local disinfection of the tissues, are of paramount importance for its successful treatment.

Excision of the shaft may become necessary during the acute stage, to prevent exhaustion from profuse suppuration; this rule is not applicable if the humerus or femur is affected, on account of the impossibility of keeping the limb in position until regeneration of bone has taken place.

In most cases fixation of the limb is necessary, for the purpose of procuring rest, and to prevent deformity.

Early incision, although usually subjecting the patient to the additional danger of pyæmia, may, he thinks, be safely performed, if strict antiseptic precautions be taken. Many advantages are derived from this procedure; it gives exit to pus, enables the surgeon to examine the condition of the bone, and is of important diagnostic value. If the opening of an abscess external to the bone is followed by immediate relief of symptoms, internal disease of the osseous tissue may be excluded; but, if no relief, or only partial relief be attained, trephining is indicated to give exit to the inflammatory products within the compact layer of the bone. In some cases he simply evacuates these abscesses with the aspirator, and then washes the cavity with a five per cent. solution of carbolic acid. He also employs this treatment for sero-purulent and purulent effusions into joints, repeating the operation as often as necessary; where, however, a purulent effusion rapidly re-collects, it will be necessary to open the joint and establish free drainage. Salicylate of soda is recommended in large doses, to reduce the temperature and neutralize the infectious material supposed to be circulating in the blood. Should signs of pyæmia arise, he places his main reliance on the administration of large doses of quinine and alcohol, and the placing of the patient under the most favorable hygienic influences. After the subsidence of the acute symptoms, iron, especially the tr. ferri chlor., should be freely administered. Any dyscrasia, as syphilis, scrofula, tuberculosis, or scorbutus, should be corrected by appropriate medication.—*Chicago Medical Journal and Examiner*, January, 1880.

Peritoneal Transfusion of Blood.—Some time ago Prof. Ponfick directed attention to a new method of transfusion. He injected defibrinated blood directly into the peritoneal cavity. As advantages of this method were claimed: simplicity of operation, and the absence of danger from disturbance of the heart, brain, or lungs.

Profs. Bizzozero, of Turin, and Golgi, of Pavia, have made an extended series of observations on this subject. The experiments were on rabbits, and only defibrinated blood was used. They wished to ascertain whether the injected blood really found entrance into the vascular system. In order to do this they determined the quantity of blood by measuring the amount of hæmoglobin by means of their chromo-cytometer.

The following conclusions were reached:

1. The blood-globules entered the blood-vessels; in as short a time as twenty minutes after peritoneal injection a progressive increase of globules was observed; the maximum increase was attained on the first or second day.

2. The increase of hæmoglobin was proportionate to the quantity of injected blood, but the increase never exceeded fifty-seven per cent. of the original amount of hæmoglobin.

3. This increased globular richness lasted several weeks and longer, but after the maximum augmentation of the first or second day there was a steady decrease, though this never quite reached the original level.

4. An increase was noted in healthy animals as well as in those rendered artificially anæmic.—*Allg. med. Cent.-Zeit.*, No. 4, 1880.

Treatment of Empyema by Thoracentesis and Irrigation.—Kashimura, of Tokio, Japan, has devised a simple little instrument for this purpose. It consists of a trocar, with a stop-cock and two lateral canulas. To the latter he has attached rubber tubes, each provided with a clamp. This apparatus has been used in the following manner: both tubes were filled with an antiseptic solution and then closed by means of the clamps. One tube was connected with a graduated vessel holding the fluid for irrigation, the other dipped down into a suitable basin containing some of the same fluid. The thorax was punctured in the usual manner, the stylet withdrawn, the stop-cock closed, and the clamp of the evacuating tube loosened. Enough pus having escaped, this lower clamp was again closed, the upper one opened, and the warm irrigating fluid allowed to flow, with gentle pressure, into the pleural cavity. This was repeated until the return fluid became clear. The trocar was then withdrawn and the patient treated after the usual manner. The histories of several successful cases are recorded.—*Berl. klin. Woch.*, No. 3, 1880.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 6, 1880.

THE MEDICAL NIGHT SERVICE.

Although the fact that a medical night service in Paris is not new to our readers, the paper by Dr. Nachtel in the previous issue of the MEDICAL RECORD will call renewed attention to it. The description given by that gentleman of the origin, working, and usefulness of the system is calculated to impress the profession with the benefits which might arise by its employment in this and other cities. Arguments are not necessary to prove that most of the serious cases occur during the night-time. The human organism is then not only in a condition, by its lower vitality and its diminished power of resistance, to invite the attacks of disease, but most diseases already existing have their exacerbations during that period. For the same reason alarming complications are apt to declare themselves during sleeping hours, and it is well known that the major part of the work of the obstetrician is done in the small hours of morning. Again, aside from the usual chances of increase of dangerous symptoms during the night, there is a liability to all accidents connected with debauchery, and oftentimes these are of an especially dangerous and urgent character. But it is unnecessary to go farther to show the need of medical service during the night-time, and that such should be rendered with despatch.

With the exception of the case of the person who is picked up in the street, suffering from injury or accident, and who comes directly under the care of the police, there is no provision whatever for prompt attention to others similarly affected. The surgeons of the police are expected to attend only to such members of the force as desire them, and to such other cases as suffer from accident in the streets previous to their being sent to hospital. Thanks to a very efficient ambulance service, very few street accidents or injuries are deprived of prompt attention, nor is an admission into hospital unnecessarily delayed. But there is another class which claims the attention of members of the medical profession—a class no less liable to accident, injury, or disease, but who suffer in their lodgings, are strangers, and do not know where to send for aid. We can hardly say that numbers of such patients die for lack of attention, but it is fair to presume that, not unfrequently, serious results obtain for the want of prompt relief, which could have been given by an efficient system of night service. There is no guarantee for a stranger taken sick against the possibility that the doctor who may be called in from his neighborhood is not wholly incompetent, or is not a miserable and irresponsible quack. On the other hand, the physician who is trustworthy is not liable to respond to the call of a stranger, and balance the chance of a much-needed night's repose against the slim possibility of either adding the patient to his regular list, or of collecting the fee for his visit. If the people expect a physician to take such chances of remuneration, and, in the event of missing them, to console himself that he has done a noble act for a fellow-sufferer, they must select one whose time in the day can be occupied in making good the lost hours in the night. It is a rule with many physicians in active practice, save in very exceptional cases, never to take a new case in the night. Emergencies occurring only among families of their own patients receive such extra attention. This is a means of self-protection against overwork and want of sleep which every hard-pressed practitioner must necessarily take advantage of. Such being the case, there is almost always great delay in eventually obtaining the services of a physician who is willing to attend to the call, and it may possibly happen that the patient may die before relief can come.

The night medical service, as detailed by Dr. Nachtel, would seem to supply all the possible wants, not only of the wealthy stranger who may fall suddenly ill, but of the poor laborer, the members of whose family may be in need of prompt and efficient medical services.

The fact that such a system has been in successful operation in Paris for several years past is sufficient proof of its efficacy, and gives a promise that, with certain modifications, it may be imitated in this and other large cities.

As will be recollected, a certain number of younger medical men signify to the police of the district in which they reside their willingness to attend night calls. In case of emergency, the police officer on duty at the station acts as a messenger for the physician, escorts him to the patient's house, and returns with him if necessary. The payment of the visit is insured by a check from the officer, the money for the same being obtained either from the patient himself, or direct from the department. By this arrangement there is no possible delay; the

patient has guaranteed to him first-class medical services, and the physician is promptly paid for the services rendered.

The police are possibly the best agents for the success of such a system, inasmuch as their stations are within convenient reach, are sufficiently numerous to be available, and there officers are always on duty. As regards the physicians who are employed, there is no favor to be shown, and while a great good is done to the patients attended, the needy physicians, those of limited practice, receive a fair remuneration for their services.

Again, these physicians may not infrequently continue their services regularly upon the wealthier strangers, while with the poorer they may, under the same circumstances, obtain fees which may remunerate them for continuous attendance. Their introduction of physicians as competent and responsible men will tend to establish them in the confidence of their new patients. It is, perhaps, unnecessary to say in this connection that none but regularly educated medical men are allowed upon the lists at the police districts.

Another point in recommending the adoption of the night service system in New York is not to be overlooked. In such a form as that adopted by Paris, it does away with much of the abuse of medical charity, concerning which a great deal has been said of late. The municipality becomes responsible for the services of the physician. Otherwise he would probably receive no remuneration whatsoever. The corporation declares itself in a very practical manner in favor of paying for medical services, and establishes a precedent which may have some bearing in time to come upon the free dispensary treatment and the gratuitous hospital accommodation. Not only will such a system protect the strangers against quackery, but will help to establish some of the younger men in the confidence of the people as capable practitioners of medicine. It has such an effect in Paris, and there is no reason why it should not be equally so here.

The collection of statistics is another important matter which must not be lost sight of in the estimation of the benefits of the night service. Many important facts of disease which are now lost will be duly collected by means of a bulletin system similar to that used in Paris. If, as Dr. Nachtel says, the number and gravity of diseases occurring during the night is so much greater than during the day, the necessity for accurate statistics need not be urged. The name of the patient is not necessarily given to the public, and is only on file at the police station to prevent confusion in the records. If it were not calculated to arouse the antagonism of the surgeons of police to this measure, we might suggest that the night medical service be in reality the police medical service, and that the present medical corps of the police be on the same footing as the medical men who volunteer to do certain services for certain fees. At present, if a police surgeon is absent in attendance upon a private case, his services cannot be obtained at the station; but when a selection can be made from a number of medical gentlemen, little, if any time, need be lost.

There does not seem to be any doubt that the Committee of the New York Academy of Medicine having the matter in charge will report favorably regarding the establishment of a night service in this city. Then will come up the questions of detail, and the means which are necessary to be taken to adapt the Parisian system to our own wants. The endorsement of the regularity of the applicants for night service should properly come from the Health Board, and the list at each station should be sufficiently large to represent every neighborhood of a precinct by an available medical man. The cost of this system can hardly be an objection to its adoption, even if such a cost were excessive. The services to be rendered must of course be necessary, and, being necessary, must be paid for at reasonable rates. But the truth is, such services are not expensive. In Paris, with a million and a half of inhabitants, the nightly calls average eleven for the whole city. The ratio for our own city would be proportionably less. Compared with the expenses of maintaining a corps of police surgeons, this outlay is merely nominal.

It is, perhaps, not so much the question whether or no it may be necessary to abolish the board of police surgeons, as it is to give the system a fair trial in a perfectly independent way. If such is done, however, there will be but one conclusion regarding the usefulness of the night service, and its applicability to all the urgent needs for prompt and efficient medical aid in all times of emergency. This fact has been proven not only in Paris, but in Berlin, St. Petersburg, Warsaw, Milan, and other cities that, following its lead, have adopted a night system of medical service.

AN EXCLUSIVE SOCIETY.

THE Philadelphia County Medical Society, we are told, has resolved that none of its papers or transactions shall be published except by a single designated firm. No reporters are allowed to convey the words of wisdom of its members, or reveal the chaste secrecy of its transactions to any other than the chosen quarter. Even the speaker himself is forbidden to give to the outside world a verbal abstract of his remarks. The Society embraces a number of eminent and intelligent gentlemen, and it is presumed that it knows what is for its own good. If the new plan pleases them, and the activity of society work is increased by limiting the means of reporting it, doubtless the profession will not mind very much, but will get along very well, though thus put out in

the cold to some extent. It is not positively essential to medical progress that the Philadelphia County Medical Society publish widely its proceedings.

MEDICAL INSPECTION OF SCHOOLS AND CHARITABLE INSTITUTIONS.

The school house is an institution which will always need careful sanitary watching. There have been great improvements in its construction, and in the care for the scholars, but defects still remain, and the ignorance of teachers and school authorities will make school-buildings continually liable to sanitary evils. In view of this, and of the recent experiments in dietary economy at the Shepherd's Fold, the suggestion that we have regular medical inspection of school-houses and charitable institutions may not seem inappropriate.

Such inspections have recently been established by the French Minister of Public Instruction, the provisions of whose circular on the subject show the opportunities for good offered by the system. In each school-house and charitable institution there is a register, with the name and office address of the medical inspector upon it. In this book he records the results of his regular inspections. These inspections must be made every two weeks. They include an examination of the whole school-building or charitable institution, including halls, playgrounds, water-closets, etc. He is to take note of the lighting, heating, and ventilating arrangements, and is to examine, physically, such of the scholars as the teacher may believe to be showing symptoms of illness, as far as possible. Finally, he will indicate the number of children absent on account of illness, together with a statement of the prevalent form of sickness in the school. All the notes thus made are recorded in the register, and a copy forwarded at once to the mayor of the city.

It will be seen that such a plan as this is fruitful of good, and that there is much in it which might be adopted in our cities and larger towns with advantage. The evils of poor light, poor heat, and bad ventilation,—of ill-arranged desks, small print, and other things contributing to defective eyesight,—might be much ameliorated by systematic medical inspection. The importance of preventing any repetition of the enormities of the Shepherd's Fold needs no urging.

ECONOMY AND PLEURO-PNEUMONIA.

The thrifty legislators of New Jersey have been finding great fault at the expense incurred during the past year in stamping out the cattle-plague. About $14,000 were spent for, as it seems to them, this trivial task of inspecting 40,000 cattle. This makes about thirty-five cents for each examination, and does not appear to be enormous, especially when it is considered that examinations form but part of the work done.

We are not acquainted with the actual manner in which the cattle inspections and quarantining were carried on. It is not impossible that the work, being novel, was not conducted in the best manner. But, however this may be, it is very short-sighted economy to cripple, in any way, the efforts that have been begun for stamping out the cattle-plague. This disease has cost England, annually, $10,000,000 for the past thirty years. We have seven or eight times as many cattle as there are in that country, and if the disease once gets a foothold among the large herds of the West, the injury will be enormous. It has been proved that active measures can stamp out the disease; and that, on the other hand, a very little neglect may cause it to spread to a most alarming extent. Retrenchment and economy in this matter, therefore, should be secondary to the securing efficient measures for protecting the State as rapidly and completely as possible from the disease.

A CITY OF HYGEIA.

Some unappreciative poet once wrote the following lines:

> "You cannot call the *Lancet* gay,
> Nor quite avoid confessing,
> That Jones 'On Muscular Decay'
> Is, as a rule, depressing."

There has been perhaps in the past some excuse for the sentiment of the first line. The pervading tone of the great London journal has been, as a rule, austere, not to say heavy. Its leaders have often been very, very deep, and at all times have had something of a quieting and soothing quality. But the *Lancet* has recently learned that away off in China there is a city of Hygeia, a town whose construction and modes of life quite come up to Dr. Richardson's most picturesque ideals, as portrayed in his recent sanitary romance, called "Hygeiopolis." This discovery has aroused the *Lancet* to a display of effervescence, of lively humor, and an editorial gayety, which is quite as electrifying as the news it furnishes us. Dr. W. Wykeham Myers, surgeon to H.B.M. Consulate at Takow, Formosa, is the discoverer of this healthful elysium. It is a seaport town and bears the name of Wen-Chow, a name having, we believe, no poetic or etymological significance, but being one which might easily and unobtrusively adorn the windows of a Chinese laundry. However, the place is all, or nearly all, that Dr. Richardson's fancy painted or the *Lancet's* humor demands. Here no morbid germs dare intrude their pestilential motions, foul effluvia never arise, health boards do not exist, the graveyard only signifies old age, and ambrosial breezes fan the systems of the inhabitants into a luxuriance of physiological activity. The *Lancet* may well be gay, and suggest in its liveliness that the Health Section of the Social

Science Association, with Dr. Richardson presiding, adjourn to this delectable spot and there make a practical study of its millennial conditions. They doubtless will furnish more details than we yet possess; and these we may expect to see served up in that highly humorous style of which the *Lancet* now shows that it is master.

BOGUS MEDICAL COLLEGES.

THE *Cincinnati Lancet and Clinic* is very commendably urging the profession of its State to make efforts for the suppression of its bogus colleges. Cincinnati has four of these, and quite takes the lead in the matter of diploma manufacture. The names of the institutions are euphonious and enticing. They are: The Physio Eclectic Medical College, The Physio-Medical College, The American Eclectic College, and The American Vitopathic College. Efforts are now making to pass a bill in the Ohio legislature, "For the establishment of a Board of Health and the Regulation of the Practice of Medicine." The bill is modelled after that of the State of Illinois, which is said to have worked so well in driving out quacks.

A bill to restrict medical practice to those persons only who are actually proved competent is now before the Massachusetts legislature, and has some prospects of success. At a hearing before the committee who have the matter in charge, it was shown that there are nine legally chartered medical colleges in this country whose diplomas are either directly sold or are given without requiring any good evidence of study or fituess for practising medicine. The names of these colleges are, besides those already mentioned: The American University of Medicine and Surgery, of Philadelphia, The Philadelphia University of Medicine and Surgery, The St. Louis Homœopathic Medical College, The St. Louis Eclectic Medical College, and the New England University of Medicine and Surgery, of Manchester, N. H.

The question of regulating medical practice by law is always a difficult one, and is especially so in large States. It can be done, however, to a certain extent, as has been shown in Great Britain, Illinois, and California. The law cannot forbid particular schools of medicine, nor should it make the attempt. It can, however, see that all those professing to practise medicine have had a medical education and possess a competent knowledge of the fundamental branches of their art. This is a thing to be desired, both for the safety of the citizen and the protection of the regular physicians. Between "modest worth" and pretentious charlatanism many people will still choose the latter, and since there is danger in charlatanism, society needs some protection against it.

RESTORING THE DUTY ON QUININE.

A HEARING was given to the American manufacturers of quinine on Wednesday last, March 3d, by the Congressional Committee on Ways and Means. The manufacturers desire to show that the removal of the duty on quinine has not lowered its price to any great extent, and that the continuance of a duty on the quinine bark makes a very unjust discrimination. They claim that the duty should be removed from the raw material, and that a duty of ten per cent. on the salts would be no more than a proper offset for the disabilities under which American makers labor.

The removal of duty on quinine a year ago excited a great deal of premature congratulation, as well as of hasty condemnation. It has been said that it did not reduce the price of the drug, and that it forced the foreign article, which is inferior, into the American market.

The only unjust thing, however, in connection with the matter was the failure to remove the duty from the raw material. The price of quinine has been lowered, and it will fall still more as the artificial cultivation increases and trade adjusts itself on other than a speculative basis. Some brands of imported quinine have been proved to be better than that from Philadelphia, and it is absurd to circulate the report that the foreign drug is all of it adulterated and inferior. The previous duty on quinine created an enormous monopoly. The repeal of this duty was a wise and judicious measure. Legislation should now simply go farther and repeal the duty on the bark. The fact that this was not done before has doubtless been injurious to the American monopolists; but, as they have had years of plenty heretofore, a year of famine will not seriously affect them.

DR. CARROLL'S LETTER ON ABUSE OF MEDICAL CHARITIES.

DR. CARROLL'S letter, concerning abuses of medical charities and the non-professional conduct of some of the gentlemen connected with our public institutions, contains some very remarkable statements. We would willingly hope that such experiences are quite exceptional, but the contrary appears to be the case. Since the appearance of Dr. Seabury Jones's letter in a previous issue, we have heard of several instances parallel to the one which he related, and now Dr. Carroll adds to the list by a plain statement of facts which are calculated to give the so-called ignorant country practitioners some concern for their reputations. Let us in charity hope that the abuses of which complaints are made are committed by the assistants, whose want of experience and lack of knowledge are the only excuses for the gross injustice done to their professional brethren.

THE NEWARK CHARITABLE EYE AND EAR INFIRMARY.—This institution has been opened to the public. Attending surgeons: Charles J. Kipp, M.D.; Wm. Rankin, Jr., M.D.; and T. Y. Sutphen, M.D.

Reviews and Notices of Books.

THE STUDENT'S GUIDE TO DISEASES OF THE EYE. By EDWARD NETTLESHIP, F.R.C.S., Ophthalmic Surgeon to St. Thomas' Hospital. Philadelphia: H. C. Lea. 1880. 8vo, 309 pp.

This book was written, as the author states in his preface, for the use of students during their hospital course. After a careful perusal of the work, we believe it safe to say that it will serve this purpose as well as, if not better than, any of the numerous manuals which have appeared.

Commencing with the means of diagnosis and the methods of examination, the attention is carefully directed to the symptoms and appearances which should be noted. In the second or clinical division, the various diseases and injuries, with their treatment, are carefully described. A third and very important division—diseases of the eye in relation to general diseases, condensed in a great measure from Förster's monograph in the Augenheilkunde of Graefe and Samisch—closes the work.

The book is written in a careful and logical manner, and, though extremely concise, we have failed to notice any evidence of ambignity. It is rendered more compact and homogeneous by frequent references, by page number, to other portions of the work; repetitions are thus avoided, and we have been surprised to find how much information our author has succeeded in conveying in so small a space. Though apparently well acquainted with the German literature of his subject, he has shown his good taste by frequent quotations from the admirable writings of his own countrymen. We were particularly impressed with the lucid manner in which glaucoma is discussed. In addition to several typographical errors, the printer has inverted the figure No. 85. A careful study of the book will well repay the general practitioner, even though it should serve only as a *monitor*. It is particularly useful in the latter regard, as the subject of treatment is presented in a thoroughly conservative manner.

ANNALS OF THE ANATOMICAL AND SURGICAL SOCIETY. Volume I. 1878-79. Published for the Society, 28 Madison street. Brooklyn, N. Y. 1879. Pp. 102.

THE Anatomical and Surgical Society was organized for the promotion of the study of anatomy, surgery, and pathology, under the laws of the State of New York, in 1879. It consists of twenty-four members, of whom eleven fill the twenty-one offices of the organization. In Art. XIV., Sec. 1, we find the following additional object or end in view, to which we wish to draw attention: "Whenever the council shall judge that it is advisable for the more complete furtherance of the objects and purposes of this Society, as stated in the articles of incorporation, they shall proceed to the organization of a medical school, which shall be incorporated in accordance with the laws of the State of New York.

"SEC. 2.—The members of the council of the Society shall be members of the board of trustees of the medical school of the Society. . . . .

"SEC. 3.—In the incorporation of this school it shall be provided that, at the election of trustees, resident members and patrons of this Society, and none other, shall be entitled to vote."

The volume, with the exception of the by-laws, consists of a reprint from the "Transactions of the Kings County Medical Society," in whose monthly issue the proceedings of the "Anatomical and Surgical Club" are printed. They are collected and issued in the present volume. The cases, as a rule, are well reported and interesting, but we regret to see here what we so often find in the report of the transactions of other similar organizations, that cases are reported and put on record before the final result has been reached, thus they are very deficient in the one important item. If a case is worth putting on record it should be fully reported, and the condition of the patient, after completion of treatment, given.

The volume is well published, and reflects credit on the industry of the individual members of the Society.

BERICHT ÜBER DIE ZWÖLFTE VERSAMMLUNG DER OPHTHALMOLOGISCHEN GESELLSCHAFT. Heidelberg 1879. 8vo, 208 pp. and four lithographic plates.

This society is one of the most flourishing in the world, and we look back with pleasure to happy hours spent in listening to the papers and discussions of the genial members. Dr. H. Cohn's papers showed that the distance at which most colors could be recognized was very much greater by electric than by bright day light. Dr. Berlin found that, in disturbances to vision after injuries of the skull, these disturbances were mainly due to fracture of the base, and more especially to injuries of the optic canal. The latter condition was found in 60 per cent. of fractures of the base. The lesion was generally one-sided. In 78 per cent. of these fractures of the canal, hemorrhage into the sheath of the optic nerve was found, and this was never noticed without the fracture of the optic canal. Dr. Rählmann proposes the use of conical glasses for keratoconus, with encouraging results. Dr. Knies gives the result of the autopsy of an eye with iritis serosa, which elicited a lively and interesting discussion concerning the propagation of sympathetic inflammation. Dr. Samelsohn presented specimens of tubercle of the iris, with the degenerated portion of which he had succeeded in successfully inoculating the eyes of rabbits; these animals presented, usually after five weeks, the same growths on the iris, and also in different portions of the body. Dr. Jany reports some successes from sclerotomy in glaucoma, and also mentions some cases where iridectomy proved effective after the former had failed to relieve. The discussion elicited a number of similar experiences. Eserine is losing ground. Prof. Dor reports on the use of benzoate of soda in purulent ophthalmia. He claims that it will prevent ulceration of the cornea when used before this has commenced. Dr. Meyer claims the same for boracic acid, and Dr. Nieden adds that this latter agent will aid in the rapid dissolution of diphtheritic exudations. Stilling observed that, as a rule, the prognosis is favorable in cases where the cornea remains intact after the fourth day, with no other treatment than careful and constant cleansing. Dr. Steffan reports an extremely rare case of acute transverse dorsal myelitis (diagnosis made by Erb), which was preceded by an exudative optic neuritis some five months before the first spinal symptoms appeared. The neuritis exhibited itself in four different exacerbations, two of which reduced both eyes to complete blindness. The patient recovered from the myelitis and neuritis. V. was restored to R. $\frac{4}{5}$, L. $\frac{4}{6}$, with free fields, but green blindness remained. Dr. Talko reported the case of a soldier, twenty-one years of age, who had $V.=\frac{15}{15}=3$. Dr. Th. Leber is of the opinion that all inflammations of the interior of the eye, excepting such as can be traced to injury or similar local

causes, are due to systemic disturbances, conveyed for the most part by the circulation. He points to the suppurative choroiditis and iritis of pyæmia, puerperal fever, ulcerative endocarditis, etc., and to those rare ones coincident with typhus, pneumonia, and the like; to the hyalitis of recurrent fever, the eye complications of syphilis, tuberculosis, and rheumatism. He considers the gonorrheal rheumatism and iritis to be of systemic origin. Meyer referred to the cases of uveal tract inflammations observed in women with uterine and menstrual disturbances. Sattler claims excellent results with antiseptics in the treatment of keratitis. A solution of boracic acid three parts, salicylic acid one part, water one hundred parts, was used to best advantage. He covers the eye with absorbent cotton soaked in the above solution. He uses the actual cautery to check ulcus serpens, and claims that it is almost painless, easy of application, and absolutely certain to arrest the progress of ulcus rodens. He considers Saemisch's operation to be unnecessary. The papers of Donders and Snelling on color-blindness showed that this subject is still in an unsettled condition, and that Holmgren's method of detecting color-blindness is not without defects.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 11, 1880.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

DR. SHRADY presented a specimen of cancer of the breast, on behalf of a candidate for admission to the Society.

DR. CARPENTER also presented a specimen for a candidate.

DILATATION OF SEMINAL VESICLES.

DR. HEINEMAN presented a specimen of dilatation of both seminal vesicles, removed from a patient who died at Roosevelt Hospital. No history had been obtained during life. The seminal vesicles were the seat of cystic degeneration; measured 2 in. in length, 1½ in breath, and ¾ in thickness. They contained a brownish mucoid fluid, which could by slight pressure be forced through the ejaculatory duets, and which, upon microscopic examination, revealed the presence of well-developed spermatozoa.

Medical literature recorded, up to 1879, but three similar specimens, one referred to in "Pitha u. Billroth," in Göttingen, and two in possession of Englisch, of Vienna. Drs. E. Mason, G. L. Peabody, and I. Adler, of this city, had personally communicated that they each had met with a similar specimen.

Englisch, who had written upon the subject of cysts of the posterior wall of the bladder, divided them into four groups. One found as single cysts in the median line of the posterior wall of the bladder, low down; a second connected with either vas deferens; a third, cysts in the prostate gland, being really only a dilated sinus pocularis; and, fourth, cystic degeneration of the seminal vesicles.

The first three varieties might be congenital, the second and third were unilateral.

The fourth variety is usually the result of inflammatory action, and is generally bilateral.

In the specimen the thickening from inflammation of the vasa deferentia seemed to have been propagated to the seminal vesicles, and confirmed the views of Englisch. Whether such specimens were as uncommon as the literature would seem to indicate, was opened to serious doubt when it was remembered that the posterior wall of the bladder was rarely examined in the course of post-mortem investigations.

DR. MASON remarked that the specimen which he found was in a dissecting-room subject.

INTRA-LIGAMENTOUS OVARIAN CYSTOMA, WITH PAPILLOMATOUS GROWTHS EXTENDING THROUGH THE CYST INTO FUNDUS UTERI.

DR. C. C. LEE exhibited the uterus and appendages, together with a tumorous mass, showing the rare condition of papillomatous degeneration of an ovarian cyst. The specimens were removed from a maiden, aged forty-eight years, who was admitted to the Woman's Hospital, January 16th. She commenced to menstruate when she was fifteen years old, and continued to do so until forty-five, when the menopause occurred. This was three years ago. Last spring she commenced to have an irregular flow, which increased in quantity during the summer and was attended with pain. About this time she was examined by a physician, who, somewhat misled by the confused presentation of symptoms, thought that there were some grounds for suspicion of pregnancy, and sent her to Dr. Lee. Dr. Lee examined the patient accordingly, and discovered anteversion of the uterus, with elongation of the organ, a large multiple subperitoneal fibroid, and a condition which he assumed to be pelvic cellulitis in the posterior cul-de-sac. The parts were very tender on pressure, but at no point were there any evidences of fluctuation. The patient was placed upon the hypodermic injection of ergotine, and in the beginning of the winter applied for admission into the Woman's Hospital. After her admission a large-sized uterine sound was introduced on several occasions. The withdrawal of the instrument was followed each time by a more or less copious discharge of pus. Dr. Lee supposed that this was due to the penetration of an abscess, caused by the breaking down of one of the uterine fibroids. This opinion was afterward found to be an erroneous one.

In the course of two or three weeks it became evident that she could receive no benefit from treatment, and she was accordingly discharged from the hospital. On being informed that nothing more could be done for her she became worse, and in three days thereafter died rather suddenly, as the result of extreme asthenia, slightly heightened temperature, and without any evidences of fresh abdominal disease.

At the autopsy all the organs were healthy, excepting those in the pelvis.

Peritoneum.—Both visceral and parietal layers of the peritoneum were coated with yellow fibrin and pus. The peritoneal cavity contained about a quart of fluid, turbid, thin, and purulent, without offensive odor. In certain places the purulent accumulations were encysted by fibrinous adhesions between the coils of the intestines.

A large myoma, growing from the fundus uteri, projected from the brim of the true pelvis into the peritoneal cavity. By the growth of the myoma, the uterus was lengthened so that its fundus projected above the pelvic brim. A membrane (which, in fact, was the upper wall of the cyst to be described) stretched from the uterus to the rectum, on a level with the brim of the pelvis; so that a recto-uterine peritoneal pouch did not exist; over the surface of this membrane the peritoneum, intimately blended

with it, passed small round hole, about one-quarter of a centimetre in breadth, existed about the middle of this membrane, through which a brownish, purulent fluid escaped on pressure. This fluid came from the cyst cavity.

Upon removing the pelvic viscera *en masse*, it was found that the space between the uterus and the rectum was occupied by a cyst, extending from the pelvic brim to about two centimetres above the anus. It occupied all the available space in the true pelvis.

The right Fallopian tube, ten centimetres in length, lost itself, at its abdominal extremity, in the upper wall of the cyst. At the insertion of the Fallopian tube into the cyst wall, the latter presented a nodular thickening.

Near the uterus, for a distance of six to seven centimetres, the right tube was connected with the cyst wall by a portion of the broad ligament (mesenterium tubæ); from this point the tube became incorporated with the cyst wall.

The left Fallopian tube was free, fourteen centimetres in length; its fimbriæ were enlarged, vascular, and cystic, looking somewhat like œdematous *charamarilli*.

The left ovary was five centimetres long, one centimetre in vertical measurement, its surface covered with little ecchymoses. The zona vasculosa contained a number of little cavities about the size of a split-pea, with firm white walls. Some of the cavities contain solid yellow plugs.

There was no trace of the right ovary, unless the nodular thickening in the cyst, above mentioned, corresponded to it in part.

The right ovarian ligament, which was connected with the cyst wall, was thickened and shortened, and ended in the lower portion of the *mesenterium tubæ* of right side.

The cyst itself was fourteen centimetres in vertical measurement, and thirteen in breadth. It seemed to have grown first in between the layers of the broad ligament on the right side, and thence into the connective tissue between the vagina and rectum, extending behind the uterus and vagina.

On the peritoneal covering of the tumor, three distinct layers were visible: 1st, an outer serous covering; 2d, a middle fibrous tunic; 3d, an inner, thick, mucous covering. Below this the wall was composed of a single, thick, outer, fibrous coat, continuous with the surrounding cellular tissue, and an inner mucous coat.

The inner surface of the cyst was thickly beset with numerous papillomatous excrescences, of extremely soft consistence, so that large masses were readily detached from the wall. These "cauliflower-like" growths were large, and nearly filled the lower half of the cyst. The cyst contained, in addition, a brownish, thin fluid.

At one point the papillomatous growths had made their way through the intervening cyst wall and muscular wall of the uterus into the uterine cavity at its upper portion, into which they project, and presented much the appearance of primary cancer of the fundus uteri.

In the upper left border of the cyst wall was a solid nodule, about the size of a hen's egg, firm, with yellowish spots in its substance (carcinoma?).

The length of the uterine cavity was fourteen centimetres, of which six belonged to the cervix. From the fundus projected a large, firm, intramural myoma, twenty-seven centimetres in circumference and eleven centimetres in height. In the anterior and left border of the lower portion of the uterine wall was another myoma five by four centimetres.

The lumbar glands were enlarged, and over the abdominal aorta, at about the origin of the superior mesenteric, was a mass of the enlarged glands, and a tumorous mass, presenting on section a soft, reddish appearance, similar to that of the intracystic papillomata, from which it was doubtless a metastasis. No other metastases were present.

The intestines and stomach presented nothing noticeable, except a moderate hypertrophy of the mucous coat of the rectum, in consequence of the pressure of the tumor farther down.

In conclusion Dr Lee remarked that one of the doubtful questions now discussed by gynecologists was the propriety of "aspirating" the pelvic tissues in cases where pelvic abscesses were suspected to exist as a complication of pelvic cellulitis, but where the abscess, being high up and surrounded by masses of organized lymph, can be *suspected* only. The weight of opinion was tending in favor of the practice, and his experience led him to think it correct. This case, on the contrary, illustrated the confusion which might occasionally arise even from successful aspiration, as it would have been impossible either to drain the cyst, or to prevent such infiltration of the tissues as would have been rapidly fatal.

Dr. Bunnon stated that he witnessed an autopsy upon a patient of Dr. Buchler, where there was not only a papillomatous degeneration of the ovary, but of different parts of the peritoneum as well. The ovarian tumor was mostly solid, but the inner walls of some of the cysts were covered with the papillomatous growth.

Dr. Lee stated that he had seen similar developments on the peritoneum, in connection with malignant disease of the ovaries. He remarked that at one time papilloma and epithelioma were interchangeable terms, and were only distinguished from each other in regard to malignancy by subsequent pyæmic changes.

Dr. Satterthwaite remarked that he had never found any microscopical differences between the two forms of growth, and clinically they were not distinct from each other except in secondary manifestations in other parts of the system.

Abscess of Liver—Ulcers of Mucous Membrane of the Large Intestine.

Dr. Rhoton presented a specimen of the above, with the following history:

Alex. Mousty, æt. 48; France; married; shoemaker; admitted to St. Luke's Hospital, December 18, 1879; service of Dr. Andrew H. Smith.

Five months before admission patient felt something give way in the region of the liver. Since then he had pain at this point, and had much diarrhœa. There had been slime in his passages, but no blood. Appetite was voracious; was much emaciated; urine normal; physical examination showed nothing. On December 23d enlargement of the liver was made out. Consultation was held December 30th. With one exception it was believed that abscess of the liver existed. This gentleman believed it to be either hydatids or malignant disease. The tumor was aspirated and about an ounce of bloody fluid obtained. On microscopic examination by two members of the attending staff, this fluid was found to contain leucocytes, red blood-corpuscles, detritus, and some large cells, which were believed to be liver-cells. On January 6th, when fluctuation had become distinct, the tumor was aspirated and twenty-eight ounces of bloody, purulent fluid withdrawn. This, on microscopic examination, proved to be the same as that

above mentioned. Up to this time the diarrhœa had continued, the patient having from four to eight thin, slimy, olive-green passages daily. Pil. opii et camph. was now given every four hours, and by it the diarrhœa was controlled. When the pills were stopped, or reduced in frequency, the diarrhœa returned, again to be controlled by their administration. This condition continued up to the time of the patient's death. On January 13th there was another consultation. One distinguished member of the consulting staff held that there had been local peritonitis, followed by an abscess between the liver and the chest-wall. On January 17th the tumor was again aspirated, and thirty-six ounces of fluid, same as at other operations, removed. After these operations the patient experienced almost complete relief from pain; but all the time was growing weaker and more emaciated. He was urged to allow a permanent opening to be made, but refused. On January 31st a compromise was made. A trocar and canula, in size between 7 and 8, French urethral measure, attached to the aspirator, was introduced and thirty ounces of fluid withdrawn. The aspirator was then detached, and through the canula a piece of doubled silk ligature, carbolized, was introduced, and the canula withdrawn. It was expected that this would act as a drain, and a permanent opening would be gained. This, however, did not occur, no discharge escaping about the silk. The patient grew weaker, and on January 4th died from exhaustion.

At the post-mortem examination, twenty-five hours after death, the peritoneal cavity was found to contain sixty ounces of turbid serum, with considerable sized flocculi of fibrin floating in it. The liver was enlarged and fatty. There were firm adhesions about the points where the needle had penetrated at the aspirations, also laterally to the chest-wall, to the right kidney, and in other places. On removing it the liver substance gave way at the point where it was attached to the chest-wall laterally, and a large quantity of thick pus and masses of necrosed liver-tissue flowed out. The abscess occupied about two-thirds of the right lobe; its walls were ragged, and thinnest at the point where it gave way and next the kidney. About an inch and a half of the silk tent, introduced at the last operation, was found extended into the cavity of the abscess. The ileo-cæcal valve was thickened, and just above it was a Peyer's patch that looked cheesy. The mucous membrane of the colon and rectum was thickened, congested, and studded with ulcers, in size from a pin-head to a split-bean. They were found in greatest number in the caput coli, decreasing somewhat in number toward the sigmoid flexure. Below the sigmoid flexure they were comparatively few in number, and the congestion and thickening of the mucous membrane was much less than further up the gut. All the other viscera were healthy except the lungs, which contained small points of fibrous phthisis at the apices.

Dr. Ridlon stated in conclusion that he would like to ask, if there was ever any beneficial results from aspiration in cases of this kind, if it would have been possible to induce healing of the ulcers in the colon by topical applications to the few ulcers in the rectum?

Dr. Lee asked if the abscess of the liver showed any pyogenic membrane, and was answered in the negative. He stated that his reason for asking the question was to remind the members that when the pyogenic membrane was present, mere aspiration was not apt to cure the abscess. He referred to a case of hepatic abscess, under his own care, in which the disease originated in a pelvic cellulitis. The patient died in due time, and the liver was presented. In that instance a distinct pyogenic membrane was found. He believed that such a condition of things usually obtained in abscess of the liver, although the contrary was stated by those who advocated aspiration. If a pyogenic membrane existed, there did not seem to be any chance of healing the abscess, unless by free drainage through an incision, and the obliteration of the sac by granulation.

Dr. Wyeth remarked that free incision had been practised in several cases with success. He thought that it was exceedingly difficult to draw pus through an aspirator.

Dr. Wyeth asked if there were any cerebral symptoms in Dr. Lee's case, and received a negative answer.

Dr. Satterthwaite stated that the material which filled the cavity in Dr. Ridlon's case was sloughy and gangrenous, and consequently could not have been drawn through an aspirator.

Dr. Lee referred to a paper on abscess of the liver, by Dr. Davis, published in a recent number of the *New York Medical Journal*, and in which free evacuation was attended with success. A very large number of cases were recorded.

Dr. Putnam-Jacobi stated that Dr. Davis's cases occurred in Mexico, were not associated with colitis, and were not metastatic in character. The point he made was to open immediately with the trocar, instead of provoking adhesions by the previous use of caustic. He then claimed that when collapse of the abscess occurred, there was no chance of disturbing adhesions, and thus inviting peritonitis.

Dr. Wyeth remarked that such an operation was performed upon the late Gen. Breckenridge, and was supposed to have caused his death.

Dr. Briddon had seen a case in which free incision was followed by recovery.

Dr. Mason had met with three, in which incision was made after the presence of pus was detected by the aspirator.

Dr. Satterthwaite believed that free incision in Dr. Ridlon's case would have given a better chance than aspiration. The abscess was also interesting as occurring in connection with dysentery. The association of the two diseases was not common in this latitude.

Dr. Carpenter had seen two cases of hepatic abscess occurring in persons who had chronic dysentery.

FIBRO-SARCOMA OF ORBIT, WITH CYSTOID DEVELOPMENT.

Dr. C. S. Bull presented a specimen of fibro-sarcoma of orbit, removed from a man æt. 49, with the following history:

The eye had been enucleated twelve years before for an injury, and the man had noticed nothing wrong until about a year before I saw him, when he began to have some difficulty in retaining his artificial eye in place. This difficulty increased until it could not be introduced, and then he began to think his orbit was filling up. When I saw him the orbit was filled up to the level of the bony margin by a subconjunctival growth, which was covered by smooth conjunctiva, was painless and slightly movable. The growth was removed entire with the conjunctiva covering it, instead of dissecting up the latter. It was easily removed, there being no firm adhesions anywhere except at the apex of the orbit. It proved to be quite vascular and very brittle. No trace of the optic nerve is visible, but some of the sections examined show traces of the muscles of the eyeball. Examination showed the growth to be fibro-sarcoma, though

the cellular element formed the main bulk of the tumor. There is also a tendency to the development of cystoid cavities, traversed by trabeculæ and more or less filled with cells, these latter being of the small, round variety, while the main mass of cellular elements were fusiform.

This is not at all a common condition of affairs in the recurrent fibroid, and hence I am not inclined to designate this tumor as such. Its origin is to me as yet unexplained. There is no history of any tumor in the eye enucleated. The growth in the orbit did not become perceptible to the patient until nearly eleven years after the removal of the eye. And I do not feel inclined to attribute its growth to the irritation caused by the presence of an artificial eye.

HERNIA STRANGULATED IN THE CANAL OF NUCK, DIVERTICULUM, OFFSET, OR DOUBLE SAC—"HERNIE EN BISSAC" OF THE FRENCH WRITERS.

Dr. Briddon exhibited a specimen of the above, and remarked: On the night of the 29th of January I was requested by Dr. William C. Hunter to see one of his patients, and from him I received the following history:

Cornelia Carunn, æt. 52, widow, and by occupation laundress. Twenty-five years ago, without any assignable cause, she found herself the subject of right inguinal hernia. From time to time since its appearance she has had attacks of more or less complete strangulation, which have been overcome by taxis applied either by herself or medical men. She remembers having been told by one or more of the physicians who saw her in the attacks, that the tumor did not wholly disappear; "something remained that would not go back." During a fit of coughing on the morning of the twenty-ninth, the bowel descended and she could not reduce it; a physician near at hand applied the taxis and failed. Dr. H. saw her at 4 P.M. same day, at which time she was suffering much pain and had vomited once. Herniæ tumor, size of a goose-egg, was found in the canal of Nuck; it was tense and moderately tender on handling; near the neck of the tumor, and externally to it, was found a second protrusion the size of a large chestnut, distinct from the larger mass. This was regarded as the latest descent, and the taxis was first applied to it with success, as was manifest to the doctor and patient. The larger mass resisted all proper manipulation to effect its reduction. Anæsthesia was not employed, the patient having a mitral systolic murmur.

I (Dr. Briddon) saw the patient at about seven P.M., and found things precisely as represented by Dr. H. The amount of fat about the region involved precluded a very accurate estimate of the anatomical relations of the parts; the right side of the mons and labium was larger than the left, and appeared to contain a doughy mass that certainly was not intestine; and about an inch and a half to the outside of the spine of the pubes was a deep-seated globular swelling, about an inch and a half in diameter; dissecting the coverings from this latter mass was difficult, so intimately were they incorporated with the sac, which was itself much thickened. Both the doctor and I had suspected that this was a protrusion from the femoral ring, but it was now found to be above Poupart's ligament. The sac was opened and found to contain nothing but omentum. After dividing the stricture above, to my surprise I found it impossible to reduce the mass, so I ligated it high up and cut it off; but even then I failed in my efforts to replace it. Passing my finger well up and around the stump of omentum, demonstrating that there were no adhesions, I detected an opening in the neck which passed into another sac, and through this the finger could be passed downward into the labium. This pocket was evidently in the canal of Nuck, and was filled with a mass of adherent omentum. On shutting it down the protrusion was found firmly connected to the fundus of the sac by two strong cord like bands. These were divided with the knife; the whole mass was transfixed with a double ligature and cut off. The contents of both sacs were now found to be continuous, and there was no longer any difficulty in returning the stumps into the abdominal cavity. The wound was closed in the usual manner, and the patient was placed under the very moderate influence of opium.

I saw Dr Hunter eight days after the operation, and he informed me that she was doing very well.

INTERNAL URETHROTOMY IN A WATER-LOGGED ALBUMINURIC SUBJECT. DEATH. POST-MORTEM REVELATIONS REGARDING MAISONNEUVE'S URETHROTOME.

Dr. Briddon presented the male genitals removed from the following case:

John Bradley, fifty-four years; brown skin; cook; widower; was admitted to the hospital department of the Colored Home, January 15, 1880. Family history unimportant; has been a hard drinker; had malaria when young, but no rheumatism; enjoyed good health until two years ago, when he began to suffer from headache, backache, and nausea; he then noticed gradually increasing swelling of the lower extremities; subsequently he had cough, with occasional expectoration of blood, and was annoyed with shortness of breath and palpitation of the heart; for some time he had experienced difficulty in emptying his bladder, the stream being very small and the desire to urinate occurring every hour during the night. At the time of his admission his urine contained thirty per cent. of albumen.

Physical examination—Heart.—Aortic valves close harshly; left side of chest much sunken in and almost motionless; percussion over right lung fair; left slightly dull over whole surface; right dull at apex posteriorly, otherwise normal; left respiratory murmur suppressed, except in interscapular space, where it is rude, dry, and moist. Râles heard over whole surface of lung.

Marked œdema of lower extremities.

Prostate normal; No. 1 olive-tipped soft bougie can with difficulty be introduced into the bladder, conveying the impression that a number of strictures existed in the penile portion of the urethra.

Diagnosis.—Old pleurisy, chronic renal congestion, urethral stricture, cystitis.

Jan. 5th.—Dr. Briddon expressed the opinion that there was no possible chance of amelioration of his bladder difficulties but through either cystotomy or urethrotomy, fully recognizing the danger of any operation in such a subject. Internal urethrotomy was done with Maisonneuve's instrument, and No. 30 French sound was passed into his bladder. On the 6th, he had suppression which lasted twelve hours, when the renal secretion was reëstablished, but the difficulty in his breathing increased and he died on the 9th, in a condition of uræmic coma.

Autopsy, nineteen hours after death.—Body fairly nourished, œdematous; rigor mortis marked. Brain not examined. Heart hypertrophied; 22 ounces in systole; cavities filled with dark clots; aortic valves slightly thickened at their bases; aorta contained a few fatty patches; considerable serum in præcordial sac.

Lungs.—Right, in condition of hypostatic congestion; left, the pleural sack was filled with clear serum, compressing the lung upward and backward, being carnified. Liver amyloid, spleen normal, kidneys small, contracted, and granular.

Penis was opened along the dorsum; the mucous membrane was found incised along its inferior surface from the meatus to the bulbous portion.

In this connection Dr. Briddon referred to a specimen which he had presented some years ago to the Society, in which the same condition of the urethra had been found after operation with Maisonneuve's instrument. These are the only two cases in which he had been able to demonstrate it. Death, in both cases, occurred from causes that could not be controlled. He had used the same instrument in a large number of cases in which there was no kidney complication, and with the happiest results, but he had no doubt that if the urethras could have been examined, the same long incisions would have been found.

He would also refer to an operation that he had done in the same institution on the same day that the internal urethrotomy was done. There was a patient in the hospital prostrated with recent right hemiplegia; he had a stricture that was regarded as impassable, and his bladder was for some time aspirated twice a day. On January 5th, he was etherized, an external urethrotomy was performed, and he had no bad symptom whatever following the operation.

Dr. Wyeth exhibited portions of tumor removed from the right breast of an unmarried woman. The patient was first operated upon in 1878, by Mr. Pollock, of London, who removed a tumor from her breast. Recurrence took place six weeks after. In January, 1879, it had attained the size of a fist. Dr. Wyeth removed it at that time, cutting clear of the growth and in sound tissue. The patient had done well since the operation, there being no return of the disease. He was inclined to believe that the growth was a simple adenoma, but could not understand how it could reappear after the complete excision of the breast, and when there was no glandular tissue from which it could spring.

AMPUTATION IN UTERO.

Dr. Blake presented a specimen of amputation in utero, with the following history:

It was a portion of the tibia and fibula of a boy of twelve, which I amputated some years since, for painful stump, with a perfectly satisfactory result. You see here the nerve which probably was the seat of the neuralgia. Now, there would be nothing in this case worthy of especial attention were it merely a specimen to serve as a text for impressing the surgical lesson that one can hardly be too liberal in the matter of flaps in an amputation. But I was informed by the family, and have every reason to believe, that this amputation was congenital, and took place in utero (as they believed), in consequence of a disagreeable impression made upon the mother early in gestation by the sight of the stump of an amputated humerus.

It is so long since this occurred, and as in the hurry and worry of a provincial practice I kept no notes of cases, I cannot remember whether there was anything but the stump at birth, but I have the impression that there was, and that there was a very ill-developed ankle and foot, attached by a thin flap of skin only sufficient to allow some circulation and nerve-power to pass, but only enough to sustain the most rudimentary condition of development of all the parts.

SUPPURATIVE FIBRINOUS PLEURITIS SUPERVENING UPON BRONCHO-PNEUMONIA IN A CHILD.

Dr. Putnam-Jacobi presented the lungs removed from a child three years old. The patient was brought to the dispensary of the Mount Sinai Hospital, January 30th, and was found to be suffering from quite extensive pneumonia of left lung, and had a temperature of 104° F. She saw the child only three times during its illness, death occurring February 10th. The last time the child was brought to the dispensary it was very feeble, temperature 101°, tubular breathing, which was very feeble over the base of right lung. The mother was not in a condition to take good care of the child, consequently it was ill-fed and did not receive the proper amount of stimulants. It was partly due to this circumstance, and partly to the fact that inflammation supervened upon whooping-cough, that an unusual result of inflammatory broncho-pneumonia occurred.

The mother, not being able to bring the child, reported that it was better and very quiet. The latter state was, of course, ominous of evil. In the evening of that day it was seized with a convulsion, which was repeated during the night, death occurring on the morning of the 10th. At the autopsy the brain was very much congested. The veins of the middle and posterior lobes of both hemispheres were much distended. There was also some distention of the veins of the inferior surface of the cerebellum. As was anticipated, the heart contained an antemortem clot. The clot was white, tough, and fibrinous, and occupied both cavities. Dr. Jacobi estimated that it had formed during the day previous to death, and at the time when the convulsions marked a change in the cerebral circulation. There was also a large fibrinous clot extending into the pulmonary artery and closely adherent to the papillary muscles of the right ventricle. Extending over the whole inferior lobe, and part of the upper lobe of the left lung, was a thick fibrinous effusion, infiltrated with pus. The underlying lung-tissue was somewhat collapsed, accounting for the diminished tubular breathing heard during life. The upper portion of that lung was in the condition of ordinary broncho-pneumonia. In the right lung there were nodules of broncho-pneumonia, with emphysema.

The point of interest in the case was the occurrence of suppurative fibrinous pleuritis, supervening upon broncho-pneumonia, in a child.

Correspondence.

ABUSE OF MEDICAL CHARITIES, AND UNPROFESSIONAL CONDUCT OF CLINICAL EXAMINERS.

To the Editor of The Medical Record.

Sir:—The letter of Dr. Seabury Jones, in your issue of February 14th, touches an abuse of which glaring examples are almost daily occurring; and, if the time be ripe for its discussion, I beg leave to contribute to the harmony of the occasion a few out of many illustrative instances which have fallen under my notice. Names, dates, and places are suppressed for the same reasons that Dr. Jones gives.

I. A boy, the son of well-to-do tradespeople, suffered a comminuted fracture of the lower end of the humerus, extending into the elbow joint, and giving

rise to severe synovitis. He was attended by a thoroughly competent physician, who, in view of the gravity of the case, called in consultation Dr. W. C. Anderson, a surgeon whose reputation is familiar to most of your older readers, and, under the joint care of these gentlemen, recovery ensued with a more useful joint than is commonly seen after similar injuries. Some months afterward, the parents, incited by village gossips, took the patient to a college clinic in New York, whereat the officiating "Professor" is alleged to have stated that the case had been ill treated, and that the only resource to escape crippling for life was to let him, the said "Professor," refracture the arm and set it properly. Making every allowance for possible exaggeration on the part of the parents, it is certain that this adverse opinion was forcibly enough expressed to induce them to threaten a suit for malpractice, and consequently I was asked to examine the boy. There had apparently been a transverse fracture, with separation of the condyles of the humerus; a good deal of exudation and induration existed about the joint; but the general relations of the parts were well preserved, and he could easily place his hand upon the back of his head, and extend his arm to an angle of about 130°; a result which I think most surgeons would deem very satisfactory, considering the character of the injury, and the history of the case. Not only was grave injustice done to an educated and painstaking physician in this case, but the people to whom such a damaging opinion was given, were in no respect fit recipients of "advice gratis."

II. A patient under the care of one of my friends, who is a skilled gynecologist, was induced to apply at a well-known special hospital; her trouble being an uncomplicated anteversion of the uterus. One of the assistant surgeons made an examination, introduced a pessary, and cautioned her on no account to permit any "country doctor" to treat her, as none of them knew how to use such instruments.

III. An elderly woman, with a forward luxation of the shoulder, was attended by a neighboring practitioner shortly after the accident. Much inflammation and pain supervening, I saw the case in consultation, and satisfied myself that the luxation had been reduced, and adequate retentive means adopted. As is usual among the lower classes, it appears that her physician's directions were neglected, and she passed from under his observation for some weeks, when she again "turned up," with a menace of a suit for damages, based upon the alleged opinion of another assistant surgeon at a city hospital, who, as she averred, told her that her shoulder had never been properly "put in joint." I may add, that about two months after her hospital treatment, she was admitted to the Smith Infirmary, on Staten Island, where I assisted in again reducing the luxation, the head of the humerus being firmly fixed under the clavicle. I have little doubt that since then the displacement may have recurred, and afforded further occasion for a hospital criticism on suburban surgery.

Aside from such explicit or implied condemnation of private practitioners (which is not wholly confined to hospital and college precincts), it occasionally happens that "out-departments" and clinics are made to conduce to the pecuniary profit of some of the officiating staff, where inquiry has shown that the patient is not in destitute circumstances, but has not been pushed to the inquisitorial extent of ascertaining whether the case were already under treatment or not. More than a few office fees have been drafted from college waiting-rooms by shrewd young gentlemen who were fortunate enough to be on the "clinical staff" of the attending professor; indeed, I was once informed by one of these rising lights that the facilities for thus building up a paying practice constituted the chief attraction of his position. I have even known of a distinguished professor himself transferring from his clinic to his private emolument a patient whom he found able to pay a fee, and who had been paying fees to another physician. And dispensaries offer a still wider field for this sort of exploration; e. g., a mechanic's wife, having an elongated cervix uteri and "pin-hole" os, went to one of the up-town dispensaries for advice. The physician told her that her case required more attention than he could give to it at the dispensary, and required her to come to his office, not omitting to mention his charge per visit. She went to him several times (paying a fee on each occasion), and was treated by means of a tonic mixture and the introduction of a Smith's pessary, for which he charged her one dollar extra (a profit of 100 per cent.). It is scarcely necessary to observe that, beyond an increase of vaginal leucorrhœa, no great alteration of the morbid condition was effected by this means.

Examples of both forms of abuse of medical charity might be multiplied; but I have trespassed far enough upon your space, and leave to others the extension of the list.

I am, sir, yours, etc.,

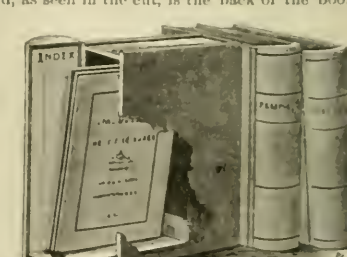
ALFRED L. CARROLL.

NEW BRIGHTON, N. Y., Feb. 20, 1880.

New Inventions.

A NEW PAMPHLET-BOX.

THOMAS L. CLACHER, of this city, has devised a pamphlet-box, which will be very useful for library purposes. It is made to represent a handsomely bound book, but it is in reality a box with a spring lid. This lid, as seen in the cut, is the back of the book, and



works by a hinge arrangement. It shuts of its own accord, by means of a steel spring concealed and embedded in the cover. The bottom of the box on which the pamphlets rest is movable, and, when drawn out, brings the contents of the box with it. By this means, also, the lid is kept open. On the inside of the lid is an index. The mechanism is very simple, fulfils all the indications required, and makes it possible to consult the contents of the box without its removal from the library shelf. It is decidedly the best thing of the sort we have seen, and, being made of different sizes, can be used for any kind of pamphlet or periodical.

A MAGNIFIED INDEX FOR THE FEVER THERMOMETER.

J. Gall & Co., of this city, have made a very useful improvement of the fever thermometer. On account of the fineness of the index of the ordinary thermometer there is great difficulty in reading it, and not infrequently it is impossible to estimate the fractions of a degree. Gall's new thermometer obviates these difficulties by simply fusing a sectional part of a convex cylinder of a very short focus on the outer surface of the stem of the instrument. By such means the index is magnified at any point of the scale to such an extent as to be readily observed. When reading the temperature it is only necessary to hold the tube horizontally, when, with a slight rotation between the fingers, the proper position of the highest magnifying power of the index will be produced. Each thermometer is provided with a gradually tapering constriction near the bulb. Any mercury passing the constriction remains above and answers as an index. Even if all the mercury is shaken into the bulb, a new index will form any time as soon as there is a rise of the mercury above the constriction.

A CLINICAL SURFACE THERMOMETER.

A clinical surface thermometer, by the same makers, is quite an efficient instrument. It is constructed of a flattened spiral-shaped bulb, from which centre the stem and scale rise at right angles. The bulb is surrounded by a rubber cylinder closely fitting to the stem and open on the bottom, thus confining the heat radiating from those parts of the skin that are to be examined for temperature. We would suggest that the index be magnified in this, as in the plain thermometer.

Obituary.

WILLIAM MAXWELL WOOD,

LATE SURGEON-GENERAL U. S. NAVY.

Surgeon-General William Maxwell Wood died March 1, 1880, at his residence, Owing's Mills, Baltimore County, Md., in the seventy-second year of his age. He was born in Baltimore, and was appointed an assistant surgeon in the Navy on May 16, 1829. Some of his most valuable service was rendered when attached to the Pacific Squadron, 1844-6. Commodore Sloat wrote to him: "I am most happy to acknowledge the very important services you rendered the government and the squadron in the Pacific under my command at the breaking out of the Mexican war. The information you furnished me at Mazatlan from Gaudalaxara, at the risk of your life, was the only reliable information I received of that event, and which induced me to proceed immediately to California, and upon my own responsibility to take charge of that country. I have always considered the performance of your journey through Mexico at that time as an extraordinary feat, requiring great presence of mind and address. How you escaped from the heart of an enemy's country, and such a people, has always been a wonder to me, and has been so characterized on all occasions." The Chairman of the Naval Committee of the Senate commented on his services in very flattering terms. Later, Surgeon Wood took part in the Chinese war. During the rebellion he was Fleet Surgeon of the North Atlantic Blockading Squadron. In 1868 he was appointed President of the Examining Board, was Chief of the Bureau of Medicine and Surgery in 1870, and was retired in 1871. His wife survives him, and he leaves a family of sons and daughters. One of his sons is in the army, and another in the navy.

St. Michael's Hospital, Newark, N. J.—The staff of this hospital has been reconstructed, and is as follows: Drs. W. O'Gorman (Medical Director), J. A. Nichols, A. N. Dougherty, Wm. Pierson, Jr., F. Wilmarth, Leslie Ward, Van Wagenen, and J. C. Young. Dr. Dougherty was elected President of the Board, and Dr. Young, Secretary. Drs. Callan and Delaney, of New York, take temporary charge of the eye clinic.

New York College of Dentistry.—The fourteenth annual commencement of the New York College of Dentistry was held at Chickering Hall, Tuesday evening, February 24, 1880. The valedictory was delivered by Edwin W. Knickerbocker, and the address to the graduates by Rev. John P. Newman, D.D.

Favorable Report on the Lunacy Commission Bill.—The House Committee, to whom was referred the bill for the creation of a lunacy commission, have reported it back favorably.

Rush College, Chicago.—The annual commencement of Rush Medical College took place February 24th. One hundred and forty-four graduates received the degree of doctor of medicine. One of these was an honorary degree. Prof. H. M. Lyman delivered the address. In the evening the Alumni Association of the college had its annual reunion and banquet at the Grand Pacific Hotel. The Alumni, faculty, and other guests who sat down to the dinner, numbered 307. Among the speeches was one by Governor Cullom, in which he took occasion to express, in a most positive manner, his support of the Board of Health in its work of ridding the State of quacks.

Medical Inspection of Public Schools. — The French Minister of Public Instruction has addressed a circular letter to the prefects of all the departments, urging them to organize, in their respective districts, corps of medical inspectors of the public schools. The duties of the inspectors will be to visit

these heads at certain intervals, to see that the bubble tubes are kept in a salubrious condition and that the rules of hygiene are strictly fulfilled; to watch over the health of the pupils, and give good advice to the teachers and heads of families, and, when possible, to furnish information for the use and guidance of the government. In some of the large cities, notably Paris, such corps of sanitary inspectors are already in existence, and the results of their labors are said to be very valuable. The latter concludes with the usual compliment to the medical profession for the well-known readiness of its members to devote themselves to the service of the public. It is evidently the opinion of the minister that a sufficient number of capable medical men can be readily found in each department who will be willing to act gratuitously as inspectors, but he suggests that, when necessary, a small salary may be voted by the communes interested.—*Gazette des Hôpitaux.*

Tetanus and the Calabar Bean.—Dr. G. G. Davis, of Frewsburg, N. Y., writes: I take this opportunity to record a case of traumatic tetanus, from a slight wound in the ball of the great toe. The wound was poulticed thoroughly; large doses of bromide of potash, chloral hydrate, and a fluid preparation of calabar bean and whiskey, were the remedies. It was observed that the action of the bean was evanescent. It was given in doses large enough to produce great prostration, then whiskey was exhibited to keep up the heart's action; also, during the profound action of the bean, forty grains of chloral were administered without obvious effect, which antagonism, I see, has been noticed by Ringer. These means served to render the case chronic, and bromide of potash, morphine, and chalybeate tonics, produced a perfect, though very tedious convalescence.

Treatment of Transverse Fracture of the Patella with the Wire Suture.—Dr. J. E. Van der Meulin, of the University of Utrecht, reports to the *Lancet* the first case of transverse fracture of the patella ever treated with the wire suture. It was one that came under his care, July, 1878. The patient was a woman aged forty-four, with a complete transverse fracture. A blood-coagulum could be felt between the parts. A longitudinal incision was made under Lister, the coagulum removed, the parts washed with carbolized water, and the fragments brought firmly together by a single platinum wire suture, which did not pass through the bone to the posterior surface. The fibrous tissue in front of the patella was united by by catgut sutures. The result was perfect. Four months later the patient came back, and instead of depression in the place of fracture, a slight ridge of callus could be felt. Dr. Van der Meulin says that by the eighth day inflammatory adhesions are formed, which shut off the cavity of the joint from the posterior surface of the patella.

Dr. Henry Le Baron Hartt, son of Dr. Henry A. Hartt, died Feb. 18th, at his home, No. 225 East Thirty-first street, at the age of thirty-eight. His disease was malignant diphtheria, from which he was sick for ten days. He was graduated from the College of Physicians and Surgeons, and was a member of the New York County Medical Society and of the New York Academy of Medicine.

Death of Dr. Robert White.—Assistant Surgeon Robert White, of the United States Marine Hospital Service, died Feb. 19th, of consumption, at his station on Bedloe's Island, aged thirty-two. He was of Scotch descent, and took his degree in medicine from Harvard University. After graduating he entered into the practice of medicine in Boston, but afterward went abroad and studied under Professors Simpson and Lister. He was attached to the Royal Maternity Hospital, Edinburgh, as its chief resident medical officer. Upon his return to America he entered the United States Marine Hospital Service, in which he continued on active duty up to a short period before his death. While in this service he wrote a number of valuable articles upon medical subjects. Among them were: "Personal Observations of Lister's Antiseptic Treatment;" "Pleuropneumonia;" "The Nature of Contagion," which was a paper read before the American Public Health Association. Dr White's abilities and his microscopical and pathological knowledge were early recognized by his superior officers, and he was detailed by the late Surgeon-General Woodworth to investigate the yellow fever epidemic of 1878. Regardless of all personal considerations, he went south, into the heart of the epidemic, in accordance with his instructions. He was afterward detailed by the department to accompany the revenue cutter Rush on her late trip to Alaska. The results of this voyage were a valuable scientific report of the country and a large and valuable contribution to the Smithsonian Institution.

Bellevue Hospital.—The examination of candidates for the position of Junior Assistant on the House Staff of Bellevue Hospital will take place at the Hospital on Thursday, March 18, 1880, at 7 P.M. Candidates must present their applications, indorsed by two members of the Medical Board, to the Chairman, Dr. Loomis, on or before the 15th of March.

Provident Dispensaries.—"Pharmacopœia" writes us that some time ago Drs. Stuyvesant Morris, J. C. Peters, R. J. O'Sullivan, and Willard Parker, with the Rev. Drs. H. C. Potter and Hall, took a great deal of trouble in the consideration of provident dispensaries. Some good effect was made upon the hospitals and dispensaries, but not as much as was desired. He believes that provident dispensaries, if established under the auspices of a medical society and put in good hands, would be very useful. They would head off advertising quacks, stop prescribing by druggists, aid many poor people, and they might be made good training-schools for young physicians, who cannot get hospital or dispensary appointments. So thinks "Pharmacopœia."

Bequests to Hospitals.—By the will of the late Mrs. Emma Strecker, daughter of James Benkard, of this city, bequests were left to the following hospitals: $10,000 to the German Hospital and St. Luke's Hospital. About $250,000 is then equally divided among sixteen charitable institutions, among which are: Charity Hospital on Blackwell's Island, the German West Side Dispensary, the House of Rest for Consumptives, and the Woman's Hospital of the State of New York, on 49th street. The will is being contested.

Failure of the Anti-vivisection Bill.—The committee to whom was referred the bill for the prevention of vivisection have reported it back adversely.

Chicago Drainage.—The city of Chicago is in a quandary as to the disposal of its sewage. It now enters the river and is carried thence to the lake. The current of the river used to be so slow that the river water became stagnant and offensive. Pumping works were therefore erected, and 17,000 gallons of water per minute poured into the river. This has hastened the current and purified the water some-

what. But the force of the current now carries organic matter out to that part of the lake from which the city gets its water-supply, so that the latter is thought to be now somewhat polluted. Meetings are being held to see what is the best plan to pursue in the matter.

Bellevue Hospital Commencement.—The nineteenth annual commencement of the Bellevue Hospital Medical College was held Feb. 25th, in the Academy of Music, before a large audience. A large number of eminent medical men, including all the college faculty, occupied the stage. An orchestra, under Dr. Damrosch, furnished the music. The exercises took place in the afternoon, beginning at 3 P. M. Professor Isaac E. Taylor conferred the degrees upon 142 graduates. Applause and bouquets were liberally bestowed. The address was delivered by Chauncey M. Depew. He said that, in his opinion, New York was destined to become not only the first city and financial centre, but the first medical university town in the world. If Hippocrates and Galen were to arise from their tombs to-day, said he, they could not pass an examination at the Bellevue College, so great has been the advance of modern medical science. Mr. Depew's closing advice to the graduates was, "Stick and dig."

The andante from Beethoven's fifth symphony followed, after which the valedictory, by William C. Stone, of Massachusetts, closed the exercises of 1880.

Toleration of Morphine.—Dr. F. Powers, of Westport, Connecticut, writes that a woman about sixty years old entered a drug-store in the town a short time ago and called for forty-five grains of morphine. The druggist weighed it out. She then called for a glass of water, put the drug in it, and swallowed the whole. The anxiety of the druggist was somewhat relieved by her saying that she had taken morphine for forty years, and that forty-five grains was now her regular dose.

The British Naval Medical Service wants more surgeons. Men do not apply, however, owing to the poor advantages, small pay, and slow advance which are offered. The service needs to be reorganized and placed on a higher basis, as has been done with that of the army.

Transfer of the Library of the Medico-Legal Society to the New York Academy of Medicine.—The committee appointed to examine into the advisability of a transfer of the library reported favorably at the January meeting of the society. Action was postponed, however, for a month. The library is the largest but two, of its kind, in this country.

Obscure Development of Abscess of Brain.—Dr. A. Steinach, of this city, writes: "In June of last year a case of brain disease came under my care, which I think in different regards very interesting, and well worthy to be reported. A boy of nine years commenced to vomit after breakfast, and soon after strabismus of the left eye appeared. These symptoms led me to suspect an affection of the brain, and I inquired if the boy had fallen on the head, or received a blow. The mother told me that during last winter, in January or February, her son had been skating on the sidewalk, and had fallen and struck his head on the ice; cold water had been applied, after which the headache disappeared. There had been no bleeding by the nose nor ears. As the remedies against the vomiting had not much effect, the mother went with the patient into the country during the hot season. There the vomiting was less frequent, as the patient lived principally on milk and eggs. After his return to the city the vomiting became again more frequent, and the symptoms of double vision manifested itself; although, by the course of the disease, I was convinced that the boy suffered from a lesion in the nerve-centres of vision. I advised the parents to obtain the opinion of Prof. W. A. Hammond. After careful examination, with the aid of the thermometer and ophthalmoscope, he pronounced the case one of commencing meningitis, due probably to the fall of the patient. The proposed remedies were again applied, but to no effect; the symptoms became more and more aggravated, until, in the middle of November, the boy was seized with eclamptic convulsions. These were arrested by a hypodermic injection of morphine into the arm. Up to this time the patient suffered no diminution of sensibility or mobility in any limb, and there was no difficulty in speech. It was accordingly to be presumed that neither the great hemispheres nor the medulla oblongata were implicated in the morbid abscess. Soon, however, the aspect changed. The iris dilated, sensibility became weaker, and, after lingering in a half comatose state for a few days, the patient died on the 26th of December. An autopsy was permitted and made twenty-six hours after death. The scalp was removed and an examination of the skull made, but no traces of an inflammation from any bruise were detected. The cortical substance of the hemispheres was in a moderate state of venous congestion. At the base of the brain, between the dura mater and arachnoidea, was a moderate quantity of serum; such liquid was also found in the ventricles after incision of the corpus callosum. The surface of the thalamus opticus of the right side showed, in comparison with that of the left side, a grayish, injected color. It was softer and uneven. An incision into that substance opened an abscess of considerable size, comprising more than half the body of the thalamus. Two tablespoonfuls of pus-matter mixed with softened brain-substance could be removed; parts of the right hemispheres, especially in the neighborhood of the thalamus, were also inflamed and softened. The organs of the left brain were in healthy condition. We may now ask, Was the development of this abscess really the consequence of the fall of the boy during last winter, or must another yet unknown cause of it be sought for? An effusion and deposition of lymph may take place in consequence of a fall, and lay imbedded under the arachnoid, if the quantity is very small, without producing serious symptoms for a long time. 'Effusion and deposition of lymph,' says Dr. Jonathan Hutchinson, of London, in a lecture on inflammation at the base of the brain, 'is always found in the greatest quantity where the arachnoid bridges over the largest spaces, as, for instance, at the base of the brain.' Large spaces are bridged over, particularly between the nerve-centres of the middle brain, and from the hemispheres to the former. It may then require a long time until from the spot of the lymph-deposit an abscess is formed, which, by growing larger and larger, produces also more serious symptoms, and determines more clearly the individual diseased organ."

Congenital Diaphragmatic Hernia.—At the annual meeting of the Hamilton Medical and Surgical Society, January 6th, Dr. Mills presented a full-time fœtus, which, at birth, made an effort to breathe, but

"perished in the attempt." On examination, there was found a hernia of the diaphragm permitting the great bulk of the intestines to gravitate into the right chest-cavity. A part of the liver was found, almost separated by the constricting diaphragmatic band, lying in the chest-cavity. The other appearances were comparatively normal.—*Canada Lancet.*

Dr. William Erb, hitherto Extraordinary Professor of Neuropathology in the University of Heidelberg, has been appointed an Ordinary Professor and Director of the Polychnic in the University of Leipsic.

A Medical University in London.—Owing in part to dissatisfaction at the management of the London University, it is said that efforts are being made to establish a university in London which shall take in all the medical schools under its general jurisdiction.

A Quarantine Convention at Washington.—A convention of United States quarantine officials has been called to meet in Washington early in May, for the purpose of revising the quarantine rules and regulations.

International Sanitary Conference.—The Select Committee of the U. S. Senate on Epidemic Disease reported favorably, February 17th, the joint resolution authorizing the President to call an international sanitary conference.

Properties of the Sulpho-Carbolates.—From his studies of these agents, Dr. David Cerna concludes that the sulpho-carbolates (1) are poisonous to cold-blooded animals; (2) are innocuous to warm-blooded animals; (3) that they are probably not antidotal to phenic poisoning, as it has been supposed they were.

Grateful Patient.—A correspondent in Dakota Territory writes: "Your interesting and o'er-true leader in the number of the Record for Jan. 3, 1880, on 'The Doctor's Bills,' recalls to my memory a rather amusing experience I had during the earlier years of my practice. I was called at midnight to visit a gentleman who had just returned from a late dinner, where he had succeeded, by hasty eating, in lodging a large fish-bone in his throat. I provided myself with an emetic, a pair of œsophagus forceps, and other paraphernalia designed to give him relief, and hurriedly repaired to his room. I found him pacing up and down the floor with a look of intense distress and anxiety, occasionally running his fingers down his throat and gagging. He told me, in tones of despair, that he thought it was all up with him, but begged me, if the least glimmer of hope remained, to proceed at once in my efforts to relieve him. He extravagantly declared, in the generosity of spirit begot by the vividness of his fears, that he would give a million dollars to have that fish-bone removed. I assured him that such cases were frequent and ordinarily not attended with much danger, before proceeding to carry out measures for relief. His fears underwent some diminution on the strength of this, and he then declared that fifty thousand dollars would no more than repay the skill and art required to extricate the unwelcome intruder. I smiled and proceeded to introduce the forceps, but after several attempts failed to grasp the bone. His fears again induced him to mention a fabulous sum as the meed of the service that would expel the object of his terrors. I then gave him the emetic, its depressing effect causing his generosity to rise again, barometric-like, to a very high pressure. In a little while the emetic disburdened him of the greater part of his dinner, and with it up came the fish-bone. He gave a sigh and a look of relief, and solemnly looking toward me, said, 'Doctor I wouldn't have that thing in my throat again for five dollars!'

"My fee eventually resolved itself into the 'valuable experience' that the occasion afforded me."

Dr. Heinrich Zorn, of St. Petersburg, Russia, a widely known authority on epidemiological subjects, died recently in that city, of relapsing fever, in the forty-third year of his age. He was one of the first to discover relapsing fever in St. Petersburg in 1864, and published an account of the epidemic in the following year.

Answer to Correspondents.

Viscum Album as an Oxytocic.—Dr. G. L. M., Line Creek, South Carolina, writes: Within the past two weeks I have had three cases of abortion among negroes, in which Viscum Album or mistletoe had been used for the purpose. I am informed it never fails, when given in a strong decoction to produce the desired effect, viz., abortion. I desire to know if it has been described as a substance that will produce abortion.

[We believe it not uncommon for negroes to use Viscum Album for purposes of abortion in other Southern States besides South Carolina. Viscum Album has, however, already been described as an oxytocic agent. In the April number of *New Preparations* for 1878 may be found an article upon the subject, by W. H. Long, M.D., Surgeon U. S. Marine Hospital Service, Louisville, Ky., in which he specially asked the attention of the medical profession to its properties. He first began to use it in 1867, and has employed it in hundreds of cases since then, with uniform results.

Dr. Long finds it of great value in post-partum hemorrhage, in other uterine hemorrhages, and in menorrhagia. He declares that it stimulates the uterus to natural contractions, and does not, like ergot, produce continuous or chronic contractions, and that it may be safely given at any stage of labor where uterine contractions are feeble or suspended. So little is yet known of the true medical properties of mistletoe, that all communications respecting it will be welcomed. It may be given in decoction or fld. ext. The dose of the latter is one teaspoonful levery twenty minutes, until the desired effect is produced. In menorrhagia, one teaspoonful every four or six hours is often enough.—Ed.]

Private Courses of Instruction.—Dr. L. C. S., Littleton, Ill. Instruction in special branches can be obtained in classes only. There are a number of the latter in active operation in New York.

Original Lectures.

ACUTE LOBAR PNEUMONIA.

A Clinical Lecture Delivered in Bellevue Hospital,

By AUSTIN FLINT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND CLINICAL MEDICINE IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

(Reported for The Medical Record.)

Gentlemen:—The patient before you has double pneumonia; in other words, pneumonic fever, with an invasion of two lobes—one lobe of each lung. It is only in such cases, and not when two lobes of the same lung are affected, that the disease is called *double* pneumonia.

In several points of view, this case is interesting and instructive. I will read the history, and comment upon those points to which I wish to direct special attention. The patient's name is Henry ——, twenty-one years old, a painter by occupation, a native of the United States, and was admitted to the hospital November 11th. There is nothing important pertaining to his family history. He has been a moderate drinker, but he says he was in good health up to November 8th, when he thinks he "caught cold." Almost all persons who have anything the matter with the chest think they have taken cold. What the patient states regarding that is worthy of no attention. The common idea is that the large proportion of chest affections, especially the acute disorders, proceed from "catching cold." The profession has not, as yet, eliminated that traditional influence. This man thinks he caught cold because he was suddenly seized with a chill, which, he states, "lasted three-quarters of an hour." Very likely the duration of the chill was over-estimated, because a period of shivering seems exceedingly protracted to a patient. He also had pain in the left side near the nipple, but he is not able to recollect how long after the chill the pain was first felt.

The length of time varies, and sometimes from four to six hours elapse, after a pronounced chill, before the pain occurs which belongs to pneumonia. He had pain in the left side near the nipple, and at the same time began to cough. At that time he had no expectoration, but marked dyspnœa, that, doubtless, was caused by the pain, which he says was severe. He took to his bed that night, and he thinks he was feverish, because his skin was hot and he was thirsty. On November 9th the cough had increased, and he began to expectorate a frothy mucus. On that day he began to have pain in his right side. In this account there is evidence that the left lung was invaded on the 8th of November, and on the following day the right lung became involved. He did *not* have a *second chill*. That is the rule. A second chill does not occur when a second lobe, either in the same or in the opposite lung, is invaded. Here I may call attention to another point—and that is, that when more than one lung is affected, the local inflammation *does not extend from one to another*, but there is a new invasion, a second manifestation of pneumonia. So, in this case, the existence of pneumonia in the lobe of the right lung was not due to the extension of the inflammation, but there was a new local manifestation of the disease. He lost in weight, felt weak, and was brought to the hospital on the 11th, having had no treatment prior to his admission. On admission he complained of cough, pain in both sides, dyspnœa; but, aside from these symptoms, he felt tolerably well. His face was flushed, and, as you see, there is a circumscribed flush in the cheeks now; his temperature was 102½° F., his pulse was 112, and had good strength. The sputa was *rust-colored*, and in that fact we have a characteristic symptom. At that time the physical signs evidenced solidification of the lower lobe of the left lung, and partial solidification of the lower lobe of the right lung,. There was bronchial respiration, bronchophony, and marked dulness on percussion Over the lower part of the lower lobe of the right lung, perhaps one-third, there was a crepitant râle, together with the bronchial respiration and bronchophony. These signs are present to-day. There is no evidence of extension of the pneumonia from the lobe which was secondarily invaded, and that often is the fact.

We have here an illustration of what I stated, in my didactic lectures upon this affection, namely, that the lobe first invaded, as a rule, becomes completely solidified; but it not infrequently occurs that the second lobe affected becomes partially consolidated, and that the process of solidification then stops. Up to this time there has been no extension of the local affection of the lower lobe of the right lung. What was the treatment adopted? He was put to bed, and given milk for nourishment. Rest and milk—two important elements in the treatment of most diseases.

On the day of admission his urine was high-colored, had a sp. gr. of 1030, but no albumen. The disease had advanced to the second stage, the local effects of the disease had been produced, and we had a right to expect that nothing more would occur with regard to the local inflammation. At that time, then, there was no indication to attempt to render the attack abortive. It was too late for that; and yet there were present no indications for further medicinal treatment than that employed. He was able to take food in proper quantity, felt quite well, had no pain, and certainly it would not have been judicious practice to have resorted to either local or general bloodletting, purging, or the administration of tartar emetic. The *expectant plan* of treatment was pursued, meaning by that, if no indications for the use of medicines exist no remedies are used, but a willingness to give remedies, no matter how potent, if the indications justified their use.

Nov. 12th.—The patient slept well last night, and to-day feels much better than when admitted. This improvement, of course, must be attributed to the natural course of the disease, and not to remedies, for he has had none.

At 8 A.M. his temperature was 100½° F., without the use of any antepyretic measures; his pulse was 100, and his respiration 28. In the evening he had an exacerbation of fever, and the temperature was 103° F., pulse 112, and respiration 31. He continues to take milk, and to-night he takes the first medicine given, which consists of two drachms of the U. S. solution of morphia.

Nov. 13th.—The patient slept fairly well last night, perspired freely, and he is now perspiring (10.15 A.M.). At 8 o'clock this morning his temperature was 100¼° F., respiration 28, and pulse 84.

Now, gentlemen, this patient was taken with pneumonic fever last Saturday, five days ago. Up to this date his case has, apparently, progressed in the most favorable manner, and yet it is a double pneumonia, which we are accustomed to regard as a much graver

condition than when the disease involves only a single lung, or a single lobe of one lung. There is no complication in this man's case, thus far; all the symptoms being in harmony with each other. The only indication which may arise for the use of medicine, looking at the case as it is presented to us now, is, that if he have an exacerbation of fever this evening, a full dose of quinine to-morrow perhaps would diminish the amount of fever. The anodyne, such as was given last night, probably would be proper. The nourishment will be continued. There are no indications for the use of alcoholic stimulants, for he has been only a moderate drinker.

This case is interesting and instructive, because it illustrates the natural history of the disease. No treatment has been employed that has any potency, and, therefore, the disease of its own intrinsic tendency is progressing towards a favorable termination. There is solidification of the lower lobe of the left lung, and partial solidification of the lower lobe of the right lung, but we may confidently predict that the case will pursue a favorable course unless complications arise. What are the complications to which he is now liable? After this lapse of time we hardly expect that another lobe will be invaded. We may feel pretty safe upon that question. There is not much ground, after this lapse of time, to fear the development of pericarditis. The circulation is so good, the action of the heart has so much strength, there is so little embarrassment of respiration, that there is but little ground for supposing that such an accumulation of blood will take place in the right side of the heart, although the pneumonia is double, as will produce distention and incur the liability to the formation of heart-thrombus. Unless the circulation should become weaker than it now is—and there is no apparent reason why it should, yet it will be watched, and, if necessary, remedies to maintain the action of the heart will be given—the patient is but little liable to this complication which occurs so often in the unfavorable cases of this disease. So far as we can judge from the present condition of the patient, we have every reason to expect that he will progress favorably through the disease. There is one point to which I wish especially to call your attention. The fever, as is usual in a case of pneumonia, was much more marked at first than it has been since, and yet resolution of the lung has not begun. The local conditions are substantially the same as they were when he was admitted to the hospital, and yet we should not expect to have the same amount of fever because of that, for it is a febrile disease and not a purely local inflammation. The fever is not purely symptomatic of a local affection, but the local affection is the result or manifestation or local effect of the fever.

How do we determine when resolution has commenced? I think it has begun where the local affection first manifested itself—namely, in the lower lobe of the left lung; and why? It was easy to understand that the part of the lobe which was first affected in this case was the *upper* part; and now, when I listen, I find that the respiration in that portion is not purely bronchial. I think I am able to appreciate a slight vesicular quality. The respiration which I now obtain is broncho-vesicular, yet the bronchial character predominates largely. Such a case as this is interesting for study as resolution goes on, especially with reference to broncho-vesicular respiration, assuming that resolution progresses without interruption from this date. To-morrow, where I now hear only indistinct broncho-vesicular respiration, I shall be able to get respiration having a well-marked vesicular quality. As incidental thereto, the pitch is not so high, it has less tubular quality, the expiratory sound is somewhat less prolonged, and so from day to day, for a week or more, we shall be able to recognize the changes in respiration, the inspiration more distinct, the expiration less prolonged, less high, and less tubular, until we find it normal in character.

Now we have broncophony, which will continue for several days perhaps, even when respiration shows considerably more of the vesicular quality in inspiration than at present; but after a time the broncophony will disappear, and there will remain increased vocal fremitus, which will disappear when resolution is complete. Dulness upon percussion will remain for several weeks perhaps, after all the other symptoms have disappeared. The amount of dulness and its duration are proportionate to the quantity of exudation incident to the associated pleurisy. While the exudation into the air-cells is often absorbed very rapidly, the exudation upon the pleural surface is always absorbed slowly, and it will take weeks for it to disappear. So long as this exudation remains, we have dulness upon percussion.

ACUTE LOBAR PNEUMONIA.

Case II.—The history of the second case I bring before you is as follows: P——, æt. 36 years, native of United States, a housekeeper, was admitted to the hospital on the 6th of December, with an unimportant family history. She stated, on admission, that she had always been in fair health up to ten days ago. Prior to her present illness she drank various alcoholic drinks almost constantly for two months. About the first of December she began to feel chilly, had no distinct chill, and the chilly feelings were followed by fever and vomiting. Cough soon followed, and pain in the right side and back, accompanied by scanty expectoration. On admission she complained of feeling very weak, of pain in the right side, of cough, complete loss of appetite, some looseness of the bowels, and had a temperature of 101⅘° F. The urine was acid, sp. gr. 1012, no albumen. On physical examination of the chest, dulness on percussion was found over the upper part of the right lung, increased vocal fremitus, increased vocal resonance, and bronchial respiration.

The *treatment* adopted was rest in bed and the administration of half an ounce of whiskey every two hours, with milk for nourishment. The action of the heart being rather feeble and somewhat irregular, digitalis was administered in doses of ♏ xx. of the tincture t.i.d.

December 7th, morning.—Temperature, 103° F. Evening: Pulse 112, temperature 103⅘ F., and respiration 28. Her general condition remained unchanged. Treatment continued: stimulants, nourishment, and digitalis.

December 8th, morning.—Temperature 103° F., pulse 102, and respiration 36. Evening: Temperature 103° F., pulse 120, and respiration 38.

December 9th, morning.—Temperature 102° F., pulse 100, and respiration 36. Evening: Temperature 102⅘° F., pulse 105, and respiration 28. The patient has had a few loose passages from the bowels, for which ♏ xx. of Squibb's liquor opii compositus was prescribed, and the diarrhœa was controlled.

December 10th, morning.—Temperature 100° F., pulse 90, and respiration 26. Evening: Temperature 101⅗° F., pulse 85, and respiration 25. Bronchial respiration continues, but with it crepitant and

subcrepitant râles. The patient feels much better than yesterday.

There has been no treatment in this case with a view to reduce the temperature, and it is a fair illustration of the natural course of pneumonia. The pulse and temperature have fallen, although the respiration remains increased in frequency. The upper lobe of a lung in this case is affected. As a rule, cases of acute pneumonia in which the upper lobe is the seat of the local disease are more grave than when the local affection is in a lower lobe. That fact has been noted for a long time—that there is more constitutional disturbance, the nervous system suffers more severely, etc., when an upper lobe rather than a lower one is invaded. In that respect, therefore, this case is rather an exception to the rule, because it has not at any time presented alarming or unusually severe features, and resolution is going on favorably.

Original Communications.

ON THE
RELIEF OF THE DEFORMITY OF A BROKEN NOSE BY SOME NEW METHODS.

By ROBERT F. WEIR, M.D.,

SURGEON TO THE ROOSEVELT AND NEW YORK HOSPITALS.

(Read before the New York State Medical Society, at its late meeting, February 3, 1880.)

The treatment of deformities of the nose has, until recently, received but little attention from surgeons since the time of Dieffenbach. A step in advance has, however, been lately made by Mr. William Adams, of the Great Northern Hospital, London, who published in the *British Medical Journal*, October 2, 1875, an account of a new method of relieving the unsightliness and obstruction due to a distorted and depressed fractured nasal bone, as well as to deviations of the cartilaginous septum nasi. Mr. Adams recognized that all cases of broken noses might be classed under two heads: 1st. Those in which the injury is limited to the anterior or cartilaginous portion of the nose, and in which the deformity consists essentially of depression and lateral bending of the cartilaginous septum, with probably a partial displacement of the septum from its bony attachments; and 2d. Those in which the nasal bones are fractured, with more or less depression and lateral displacement, and with a certain amount of crushing and bending of the cartilaginous septum.*

Mr. Adams recommended in his paper on this subject, that the cartilaginous septum, when deflected, should be forcibly straightened with a pair of flat-bladed forceps, introduced with one blade in each nostril, and if there was also present a depressed fracture of the nasal bones, that these bones should be refractured by crowding at the same time the forceps strongly upward; assisting this manœuvre with powerful pressure by the thumb and fingers on the outside. After the deformity had thus been overcome, a pair of steel plates, secured externally by a screw, were worn for a few days, passed up on each side of the replaced septum, and making only light pressure. Subsequently separate ivory plates were introduced by the patient, and worn for a number of hours each day. If the bones had been refractured, they were assisted in their reposition by a nose-truss, so contrived that when fastened by a band to the forehead, pressure was made by screw power on the loosened bones at their greatest convexity.

Mr. Adams presented in his article three cases that had been treated by him. The first was a man whose nose had been deformed by a cricket-ball striking him on its end one month previously. The external deviation was slight, though one nostril was much obstructed by the bent septum. This latter was successfully straightened by the above-described method. The second case was one of fracture of the nasal bones, with depression and coincident bending of the cartilaginous septum, from a fall received six months previously. While the septum was easily straightened, the depression and lateral deviation of the nasal bones were not improved until after two operations had been performed. The case was not, I should judge, a perfect success.

The third case occurred in a young lady, whose nose had been hurt some six years previously by a fall of forty feet down a bank, crushing thereby both nasal bones and flattening them. The cartilaginous septum was also depressed and bent so as to project to a large degree into the right nostril. The forceps readily replaced the septum, and to some extent Mr. Adams succeeded in improving the position of the nasal bones. The final report reads, "One month later I endeavored still further to raise the depressed bones, with marked improvement, and with much of the depression removed."

I have ended the citation of these cases purposely with this quotation, as it shows, in my opinion, the demerit of this operation. For in the several trials which I have made to refracture nasal bones by Mr. Adams's method, failure has been encountered, and a departure, therefore, has been made from his plan of action, which I venture now to bring to your notice. The cause of failure in Mr. Adams's method appeared to be twofold: first, that the forceps was too large at its end to be satisfactorily carried up under the nasal bones; and second, that the fracturing force was not ample enough, notwithstanding a variation in the procedure was made of strongly opening the blades laterally, while they were introduced as high up as possible.

Another variation that I practised, after a fair trial of the above plans in three of my cases, was this: one blade of the forceps was passed inside the nose and the other outside, grasping thus the lower edge of the nasal bone, and sharp but momentary twisting resorted to, with the effect, in two instances, of breaking on one side only—in one case the nasal bone, and in the other the edge of the nasal process of the superior maxilla.

Therefore in two cases, one of which is kindly furnished me by Dr. Little, a radical departure from the refracturing process from within was taken, and the deformity most easily and satisfactorily removed by what is believed to be an original procedure. This was nothing less than to perform an osteoclastic operation, or, in more ordinary words, to make an incision (not directly to the bone, but bevelling, as Packard, of Philadelphia, has suggested, as creating the least cicatrix), not more than an eighth or a quarter of an inch long, over the greatest convexity of the bony deformity and parallel to the free border of the nose, so as to, as near as may be, strike the nasomaxillary junction, and then by the introduction, through this small cut, of a very narrow chisel,

* Watson's Diseases of the Nose, p. 305.

to cut through the bone with a few strokes of a mallet. And if the tilting action of the imbedded chisel proves insufficient to loosen the other side of the nose, it is only necessary to chisel that side also, through the first and only incision to be made. It is remarkable with what ease and rapidity this replacement can be effected, and how readily the retention of the nose in its corrected position is accomplished. In one instance, where a moderate depression existed on one side, the elevation of the refractured bone was brought about by pushing it upward from within the nose by means of a dentist's amalgam-plugger (see Fig. 1, a very excellent in-

FIG. 1.

strument too, by the way, in the treatment of recent fractures). A piece of sticking-plaster, rolled up with the sticky side out, to form a compress, is laid along the nose on its formerly prominent side, and another strip drawn across this and the face holds everything snugly in place.

The nose-truss,* a modification of Adams's, was subsequently applied, and after a few days served to prevent any displacement, though but little pressure was required to be made with it. The cicatrices, as was expected, are insignificant, and not to be seen by ordinary inspection.

CASE I.—*Lateral deviation of nasal bones to the right; failure of Adams's operation; refracture by chiselling; perfect restoration.*—The patient was a man of thirty-five who had sustained a fracture of the nasal bones by a fall down the well-hole of a stairway, in such a manner that his nose struck the baluster. The deformity produced was so great (see Fig. 2) as to carry the distal portion of the nose three-quarters of an inch to the right beyond the median line, with a marked projection on the same side of the nasal bones; no depression, however, existed. The

FIG. 2.—Before operation.

tear-duct on that side was much disturbed, and an annoying epiphora was present. No marked deviation of the cartilaginous septum.

Nov. 29, 1879: The patient was etherized, and with Adams's forceps introduced into the nose an attempt was made to refracture the nasal bones by first pressing with the instrument upward and then to one or the other side; and this not succeeding, the jaws of the forceps were forcibly crowded apart, hoping thus to break asunder the nasal bones. This failing, principally because the end of the forceps could not be carried sufficiently high up, one blade of the forceps was placed outside the nose over the nasal bone of one side, and the other blade of the forceps passed into the nose as far as possible, and by a twisting motion pressure brought to bear on the bone. Nothing was accomplished by two trials save a slight breaking-off of the lower part of the nasal process of the superior maxilla of the left side. A short bevelling incision, scarcely a quarter of an inch long, was then made over the line of nasal-maxillary junction on the right side, and the nasal bone separated in a few moments, by chiselling, from its frontal attachment. Then by tilting the nose with the chisel *in situ*, and by forcible pressure with the thumb from the outside toward the left, the other nasal bone was broken, when the replacement (see Fig 3) of the nose was at once accomplished. The nose

FIG. 3.—The result.

was secured in its new place by two strips of adhesive plaster passing directly across the face. The next day a modification of Adams's nose-truss* was applied to retain the nose in position; very little pressure sufficed to do this.

The result was a complete success. In about fourteen days the nose was sufficiently firm to allow the head-band and apparatus to be dispensed with. With the cure was noticed also a decided amelioration of the flowing of the tears. The cicatrix is now (Jan. 15, 1880) scarcely to be seen.

CASE II.—Was under the charge of my friend, Dr. Little, who was so much satisfied with the result I had obtained, that he resorted to the same operation.

The history of the case, which he has forwarded me, is as follows: The patient, a young man of twenty-nine, was accidentally struck in 1877 by an Indian (or large wooden) club. By this the nasal bones were fractured and strongly carried to the left side. At the time of the operation there was yet a decided scar over the nasal bones from the wound of the integument.

January 8, 1880: The patient was admitted to St. Luke's Hospital, and Dr. Weir's operation was performed after a trial of Adams's forceps with both blades within the nostrils, and also with one blade outside, making in the latter case a twisting motion to break the bones. These attempts failing, a small incision was made over the nasal process of the left superior maxillary bone, and with a small chisel the nasal bone of that side was readily detached, and that of the right side afterward easily broken

* Made for me by P. H. Schmidt, instrument-maker, of this city

* An ingenious spring nose-truss has also been devised by Dr. Toland, of San Francisco.—*Lectures on Surgery*, p. 453.

by the forceps, with one blade outside and the other inside the nostril. The replacement of the nose was then at once accomplished. The patient left the hospital on the 10th, so little irritation being caused by the operation; and for several days he wore Dr. Weir's retentive apparatus. This, with the use of pressure of the fingers towards the right side, sufficed to keep the nose in the normal position until the union became again firm. The photographs, before and after the operation, which accompany this case show that the restitution of the nose was perfect.

Since the failure of the Adams forceps in this case, I have had a pair constructed longer and narrower in the blades, and with more powerful handles (see Fig. 4), but have had, as yet, no opportunity to test their efficacy.

Fig. 4.—Modified Adams's forceps.

Although, in these instances, no deviation of the septum occurred, yet a fair experience in such deformities leads me to the opinion that in many instances the mere reposition by Mr. Adams's forceps and the subsequent use of his retentive nose-pads will probably not be satisfactory. The resiliency of the bent cartilaginous septum is in most cases so great that the suggestion of Goodwillie needs to be put into effect. It is to cut out with Blandin's * punch-forceps (see Fig. 5), a section of the

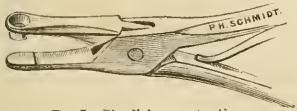

Fig. 5.—Blandin's emporte-pièce.

septum, when its replacement is much more stable, and all tendency to relapse is generally avoided. The hole made may be, if necessary, as large as a five cent-silver piece (half an inch in diameter), and yet no fear need be entertained of causing any dropping in of the nose, or impairment of its external contour. The opening in the septum, moreover, when made, becomes considerably smaller on cicatrizing, and frequently completely closes, and, if permanent, is in no way a detriment. On the contrary, if, for some unforeseen reason, a failure to relieve the deformity occurs, or only a partial success is met with, then this opening allows a free access of air from the unobstructed to the obstructed nostril.

When the deviation of the septum causes, as is frequently encountered, an almost complete occlusion at or near the external orifice of the nose, the remedy is readily applied. It is to cut off, with a sharp knife or scissors, the projecting portion of the cartilage. This little operation I have found to be facilitated by using a small double-gouge forceps, mounted like a dressing-forceps (see Fig. 6.) If the bending is great, it may be necessary to remove all the cartilage at this point; if this be done carefully, the mucous membrane of the opposite side may be preserved intact; but if a communication be established between the two nostrils above the columna, in most cases it will soon close over and certainly give rise to no trouble.

* Or, "Emporte-pièce," Dict. encyclopéd. des sciences méd. et chirurg., article "Nez."

The same instrument will serve to cut away a turbinated bone, or those not very rare exostoses from the vomer that shut up sometimes the middle

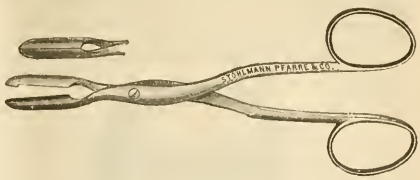

Fig. 6.—Double-gouge forceps for the nose.

and inferior meatuses. Some seven years ago I had occasion first to remove one of these exostoses, to me then previously unknown, and successfully performed it with a small chisel. On a subsequent examination of ten skulls, I found that the malformation existed in three instances. Since then it, and outgrowths like it, have been described, and principally by Prof. Harrison Allen, of Philadelphia.*

But this is a digression from my main point, which was to present not only a novel, but also a very easy method of relieving a very serious and hitherto quite intractable deformity of the human face.

I now venture to beg the Society's further indulgence in occupying their attention with an additional instalment on the subject of an original and possibly novel method of *elongating* a *shortened* nose. I trust this caption is sufficiently taking to secure me a few minutes' patient hearing. The method is at once understood by a reference to these diagrams, casts, and photographs.

The patient, a man of twenty-eight, was kicked by a horse when he was nine years of age. The nasal bones were fractured and depressed, the nose driven up and shortened, and its tip badly cut, so that the end of the columna was buried below the surface of the adjacent skin. The nares looked directly forward, and the nose was decidedly "tiptilted like a petal," as Tennyson says.

To relieve this condition, shown in Figs. 7 and 8

Fig. 7.

(from photographs), four operations in all have been performed, with a most satisfactory result. The first one, August 15, 1878, consisted in Adams's operation to straighten the wrinkled septum, and to refracture

* Am. Jour. Med. Sciences, Jan., 1880.

and raise the depressed nasal bones. Only the nasal bone on the left side could be refractured and partially replaced. The septum was not improved. At this operation the depressed end of the columna was loosened and secured on a level with the surrounding skin.

The second, and the important operation (see Fig. 8), was done on the 30th of September, 1878, in this

FIG. 8.—Showing the line of incisions in the second operation.

way: the nose was cut transversely across about three-quarters of an inch from its tip, through skin, cartilages, septum and all, to a level with the face, until it was sufficiently free to be easily depressed to a proper level. When this was done a triangular gap existed between the two edges of the cut, above and below, of nearly an inch in width. Parallelogrammatic flaps, involving the *whole* thickness of the cheek, were then cut wider than the gap to be closed in the nose (in order to allow for subsequent shrinking), with their attached bases close to the nose. These flaps, after being dissected up, were turned on themselves, so that their distal or external ends met in the median line, and were there secured, as well as elsewhere, by care-

FIG. 9.—The result of operations for elongating the nose (from a photograph).

fully adjusted black-silk sutures. The spaces whence they were taken in the cheek were in turn closed by bringing together their opposite sides. This was done easily, as the tissues adjacent were ample, creating only a linear cicatrix and after a month's delay (October 26th) the appearances presented as the results of this operation were again modified by taking out the redundant portions of skin made by the twisting of the flaps at their bases, which trimming process was again resorted to in June of 1879. Now the case is complete, and is shown in Fig. 9. The new portion of the nose, owing to the thickness of the cheek-flaps, is quite firm, and no obstruction of the nostrils exists.

SOME NEW FEATURES IN THE ANATOMY OF THE CORPORA QUADRIGEMINA.

By EDWARD C. SPITZKA, M.D.,

NEW YORK.

THE older anatomists, observing the similarity in external appearance between the anterior and posterior pairs of the corpora quadrigemina, naturally considered all the four tubercles to be analogous in their structure and relations, and therefore also in their physiology. This view they considered to be materially strengthened by the fact that in reptiles the place of the double pair possessed by the mammalia was occupied by a single pair. According to the older view, the only difference between the optic lobes of reptiles and the corpora quadrigemina of man and his allies, was that in the latter, in addition to the longitudinal furrows separating the embryonically *single* mid-brain into two lateral halves, there was formed a transverse furrow which resubdivided these, so that four tubercles resulted.

This view is erroneous, and such physiological inferences as have been based on it fall to the ground. Meynert and Huguenin, for example, attribute to both the anterior and posterior pairs the same relations to the optic tracts. Adamuk attributed to both an influence on the co-ordination of the ocular muscles, basing his opinion on the results of local irritation of these bodies, forgetful of the fact that irritation cannot be limited in the depth to which it may extend, when experiments are carried on in so narrow an area.

On discovering faintly marked, but unquestionable corpora *quadrigemina* in an anaconda snake,* I was led to make a comparative and embryological study of these bodies in different animals (including man) with the following result:

The middle cerebral vesicle of man divides into two lateral halves at a very early period. As soon as the division becomes well marked, an elevation is noticed between the subdivided mid-brain and the cerebellum, which, at first very insignificant, grows rapidly and becomes joined to the two halves of the mid-brain. It is *at all times* demarcated from the latter by a shallow sulcus running transversely. Subsequently the posterior body undergoes a division by a longitudinal furrow which appears like a continuation of the furrow separating the pair of ganglia in front of it.

All this can be traced without difficulty, in embryos between the second and fourth months,† and, confirmed by observations on the embryos of the dog, proves conclusively: 1st, that only the anterior tubercles are derived from the mesencephalon; 2d, that the posterior pair is a secondary and foreign addition, derived from the hind-brain; 3d, that the cur-

* Contributions to Encephalic Anatomy. Part VII. Journal of Mental and Nervous Diseases. 1879.

† I am indebted to Drs. Harwood, Roth, Keune, and McGuire for a very complete series of embryos of these ages.

rent description of the segmentation of the corpora quadrigemina is incorrect, inasmuch as there are not first one, then two, and finally four bodies, but first one—two—three—and then four. There is a stage when, the anterior pair being represented by two tubercles, the posterior pair is represented by a single undivided body.

These facts alone should render it desirable to subject the function of the posterior pair to a more careful scrutiny than it has hitherto received.

On examining carefully a series of microscopic sections from reptilian brains, I found that the ganglion of the posterior pair was *present* in the region of the valve of Vieussens, and had the same shape as in mammals, as well as an analogous histological structure. It could be easily shown that this ganglion (which is double) had no relations of any kind either to the optic or the oculo-motor nerves. This fact is also damaging to the older view.

Several years ago Gudden,* after extirpating the eyes of young animals, was struck by finding that the secondary atrophy induced was limited to the anterior pair. This also rendered it highly probable that the anterior pair *alone* was related to vision and the movements of the eyeball. The same observer discovered another highly valuable fact, tending in the same direction, namely, that in the practically blind mole, the anterior pair was naturally atrophic, the posterior hypertrophic. I have been able to confirm this observation and to extend it; in the case of some crepuscular bats a similar though less pronounced difference is found. A very instructive fact is remarked on comparing the corpora quadrigemina of the large-eyed pteropus (so-called fruit-bat, flying fox) with the atrophic-eyed small bats of this climate. In the former the anterior pair is very large, and (the sole instance in the animal kingdom) each anterior tubercle shows a transverse sulcus, while the posterior pair is exceedingly small. In the latter species this relation is reversed.

Forel† calls attention to the grave error into which Meynert, Huguenin, and their followers have fallen in regarding the ganglia of the anterior and posterior pairs as similarly shaped lentiform bodies. It is difficult to understand how such a conclusion could have been arrived at. There can be no greater difference than that found between the anterior and posterior pairs in this respect. The anterior pair has a true cortical structure, particularly finely marked in reptiles (iguana, tortoise), and well illustrated in a fine artotype of a specimen from the frog, taken from one of Dr. J. J. Mason's photographs. The posterior pair contains a lentiform ganglion, of a gelatinous basis structure, and more or less rotund cells with fine processes, such as are found in sensory ganglia.

Forel has also shown that the tracing of a part of the optic tract into the posterior pair, by Meynert, was based on his confusion of this with other fasciculi.

Pathological experience has shown that lesions of the posterior pair (exclusively) affect neither vision nor the ocular movements.‡ Finally, in experimenting on opossums, animals admirably suited for the purpose, as their corpora quadrigemina are not covered by the cerebral hemispheres, I have found that superficial irritation of the posterior pair, as well as destruction of the ganglia of this pair with chromic acid, did not modify the ocular movements, while irritation of the anterior pair caused the most violent nystagmus, which differed in its direction with the locality irritated.

From all these facts, conjoined with the total absence of any visible connection between the optic and oculo-motor nerves on the one hand and the posterior pair on the other, it follows:

1st. That the anterior and posterior pair are not analogous ganglia.

2d. That each pair has a different embryonic origin.

3d. That the posterior pair is different in structure and relations from the anterior.

4th. That only the anterior pair is related to the retinal and oculo-motor innervations.

5th. That the optic lobes of reptiles are homologous with the anterior pair of man alone. The posterior pair of man is represented in most reptiles by a concealed lentiform ganglion, and in some pythons by a distinct posterior pair of tubercles.

The relation of the posterior pair to the retina and ocular muscles being excluded, the question arises, What functional importance does it or may it have? It is highly probable that these ganglia have some important relation to tactile sensation, for the following reasons:

1st. Their structure is that of sensory ganglia. 2d. Their embryonic origin is from the same mass which, lower down, becomes developed into the gelatinous sensory nuclei of the trigeminus. 3d. The fasciculus connected with these ganglia (inferior lemniscus) can be clearly traced to the posterior columns of the cord through a beautiful decussation which lies in front of the pyramidal crossing. 4th. The posterior pair is hypertrophic in animals with defective vision, and in such animals it is known that the sense of touch vicariates for that of sight. The performances of the bats whom Spallanzani blinded are suggestive in this connection, when we bear in mind that their posterior pairs are very large. In the mole, with a considerable development of the sensory apparatus at the end of the snout, the same feature is found.

To return to the anterior pair, it seems to the writer that few ganglia present such excellent opportunities to the investigator who seeks to establish the principles of co-ordination on an anatomical basis.

In reptiles it is found that the ganglionic substance of the optic lobes (anterior pair in man) is covered on the outside by an expansion of the optic nerves. Then follows a series of beautiful elongated cells, arranged in a radiatory manner, with processes running towards the axis of the aqueduct. A layer of fusiform cells next follows, which is intercalated between a system of concentric fibres. Then comes the deep white matter of the optic lobes, which separates the cortical gray from the central tubular gray, the latter surrounding the aqueduct on all sides, and containing in its inferior part the nucleus of origin of the oculo-motor nerve.

The fibres of the deep white matter, which evidently originate in the cortex of the optic lobes, partly enter the oculo-motor nucleus of the same side, partly through a beautiful decussation, that of the other. A considerable proportion of the fibres does not enter either nucleus, but, changing direction, becomes longitudinal, and constitutes a fasciculus,* which, entering into relation with the trochlearis and abducens nuclei, extends uninterruptedly into the spinal cord, there to constitute the

* Archiv fuer Psychiatrie, vol. ii.
† Ibid., vol. vii.
‡ Nothnagel: Topische Diagnostik.

* Posterior longitudinal fasciculus of the tegmentum.

deepest part of the cells and of Turck, and to terminate directly and by the anterior commissure in the nuclei of origin of the cervical nerves.

It would thus constitute a bond of union between the visual impressions and the movements of the muscles controlling the eyeball, and the rotation of the head and neck. It is the path by virtue of whose existence the pigeon, deprived of its cerebrum, follows a candle-light with its eyes and head.

It is somewhat puzzling that, in animals in whom the movements of the eyeball are *associated*, as in man, the monkey and cat, the relations of this fasciculus should be essentially similar to those of reptiles, where one eye may be withdrawn by the *musculus choanoides*, and entirely motionless, while the other is protruded and moving in all directions (frog, loss so tortoise and alligator; a remarkable instance is that of the chameleon, which is able to protrude both eyes on erectile stalks, and move these in opposite directions, and in the most curious disharmony).

But anatomy must content itself with being able to point to the apparatus through which the co-ordination takes place; the *how* is a question for the physiologist. It is no more remarkable that the posterior longitudinal fasciculus should show so little variation in animals whose oculo-motor co-ordinations differ, than it is that in both reptiles and mammals the trochlearis nerve decussates in the valvula Vieussenii, although the great teacher Brucke* taught that *a priori* it should not decussate.

There could be no stronger proof for the assertion that the fasciculus in question has a close relation to the oculo-motor nuclei, and those innervations which may be interpreted as co-ordinated retinal reflexes, than that in the mole (Forel) and bat (own observation) it is defective just as the oculo-motor nuclei are absent or rudimentary.

The deep white matter of the anterior pair bears the same relation to the cortical gray of this region that the white matter of the hemispheres bears to the hemispheric cortex. And the continuation of the deep white matter of the anterior pair, as a longitudinal fasciculus, plays an analogous rôle to the internal capsule and pyramidal tract, placing lower centres under the control of higher ganglia.

We find in the cortex of the anterior pair of man and the mammalia large multipolar cells, somewhat resembling the larger pyramids of the cerebral cortex, and which tradition assigns a motor function to.† This fact supports the view that in the anterior pair we have to seek for certain motor innervations and co-ordinations.

As to the relations of the anterior pair to the appreciation of visual impressions, while it is quite evident that in lower animals they or their homologues constitute the sole visual centres, and that all visual impressions must travel through them before being projected in higher ganglia, they have lost this exclusive position in man and his allies. It would lead me too far to discuss this question at length, and I therefore content myself with referring to the fact that the gradual elaboration of a direct optic path to the thalamus, and finally to the occipital lobe through the external geniculate ganglion (against Forel), is only in accord with the general law of the development of the nervous tracts, that fasciculi running uninterruptedly to high ganglia are preceded by interrupted tracts in their formation.*

1611 E. Fiftieth Street, New York.

After the above article had been written, I was able, through a piece of good fortune, to confirm one of its propositions by a very striking observation. In seeking to establish as complete a chain of evidence for my statement that the posterior pair of the corpora quadrigemina was represented in the reptilian brain a statement supported by the discovery cited, I felt that the brains of one group of reptiles, which, in my opinion, stands far nearer the mammalia than any other, needed a thorough examination. On the 18th of February I received a perfectly fresh *iguana*, and was able to supply the missing link. It seems that in the previous studies of the most allied Lacertian brains, the observers have examined and delineated the brain as a whole, without separating and exposing the different segments; how otherwise the beautifully patent relation which I am about to describe escaped their notice I am at a loss to account for.

In this as in some other Lacertians, the cerebellum, unlike that of the alligator and tortoise, is turned upwards and forwards, its arachnoid fusing with that of the optic lobes, against whose postero-inferior contour the cerebellum is applied. On separating the cerebellum from the optic lobes, which, if done carefully, can be perfectly well accomplished, two finely-marked tubercles, small but of as plastic a contour as those of man or the horse, were revealed. The disproportion between the optic lobes and these posterior tubercles is very great, but there can be no doubt that the *iguana* has not only an anterior and posterior pair represented (as I have established for turtles, etc.), but has these bodies also *in the same relative position* as man.

That allied Lacertians possess the same character I do not doubt, for in a sagittal section of the brain of *Psammosaurus Bengalensis*, figured in Huxley's Comparative Anatomy, I find what appears to be the section of this body. That author, however, has overlooked it, for he adheres to the criterion between the mammalian and sauropsidan brain, that the former has always four tubercles, and the latter always two, which is herewith shown to be imperfect.

Other remarkable and noteworthy features were observed in the same brain, approximating it to the mammalia. These, however, will not merit an extended description until the complementary microscopical description can be furnished.

E. C. S.

The Meeting of the White Mountain Medical Society, on Jan. 28th, at Wells' River, was quite a successful one. Papers upon "Diphtheria," by Dr. Moody, on "Abscess of the Spleen," by Dr. Brown, of Well's River, and on "A Case of Fracture, with Dislocation of the Neck of the Femur," by Dr. Mitchell, occupied the most of the first day. The election of officers resulted in the choice of Dr. C. G. Adams, of Island Pond, President; Dr. C. P. Frost, of Hanover, Vice-President, and Dr. C. R. Gibson, of Woodville, N. H., Secretary. The Society adjourned to meet at Littleton, N. H., in July, 1880.

DEFIBRINATED BLOOD AS A SUBSTITUTE FOR EXTRACT OF BEEF.

By F. E. STEWART, Ph.G., M.D.,

NEW YORK.

"It is the result of centuries of observation and study," says Dr. A. H. Smith, in his article on rectal alimentation, "that disease is a burden imposed upon the economy, which can be sustained and ultimately thrown off only by an expenditure of vital energy, and that in increasing, and not in diminishing, vital force, are we furthering the reparative processes of nature." Great prominence is therefore given to supporting, instead of the former reducing, method of treating disease. Rapid tissue-waste demands corresponding supply. It is for this reason that restorative and building-up remedies are now so much in vogue. Cod-liver oil, because well fitted for furnishing carbon, is employed to reconstruct tissues of which carbon enters largely as a constituent, as well as for its tonic properties. But the most exhausting waste in acute cases is of the nitrates, and there is no corresponding article to cod-liver oil for the repair of nitrogenous waste.

Meat as a food, in health, is demanded by the appetite for the supply of waste of nitrates; but in sickness an impaired stomach refuses to digest it. Attempts have therefore been made to present meat by preparation in a form for easy assimilation. Experience, however, proves that these preparations are no substitute for meat, and the numerous extracts and essences of meat flooding the market are but records of many failures.

New Remedies for January, 1880, contains an original communication from Adolph Scheppe, on extract of meat, from which we glean as follows: "*Liebig's Extract*, and the extracts from Montevideo, San Antonio (Texas), Fray Bentos (Uruguay), are made by extraction with cold water, and subsequently heating to the boiling-point; in this way all albumen coagulable by heat, gelatine, and fat, are left behind. They therefore are not nutrients at all, but must be considered as nervous stimulants, like tea, coffee, chocolate, brandy, and similar articles." Then follows an analysis, giving the composition of Liebig's Extract of Beef and a number of other beef preparations extensively advertised. In *Johnson's Fluid Beef* it is found that the want of albumen in the extract is supplied by the addition of powdered meat. There is no advantage, however, in this over beef itself as an article of food, and surely the beef is much cheaper. *Valentine's Meat Juice* "is stated to be made by partly roasting the meat, by which process the albumen coagulates, and obtaining the juice by subjecting to hydraulic pressure. . . . This extract contains no appreciable amount of albumen coagulable by heat; by the process of roasting, a minute quantity is peptonized. Compared with Liebig's Extract it is very expensive, the price being double, and the strength less than two-thirds." *London Essence of Beef* contains more water, and less solid matter, than the meat from which prepared. It therefore cannot claim to be a condensation, and is deficient in many other points. *Mensman's Peptonized Beef* is stated by this authority to contain coagulable albumen and blood. "The presence of coagulable albumen and blood is incompatible with the process of peptonization, since both of those substances are the first to be changed in their nature, by the action of the acid necessary for the successful completion of the process." He also states that tests fail to indicate any appreciable quantity of peptone. The analysis following this statement gives but 5.76 per cent. of solids, altogether, in the preparation, while meat, freed from fat, contains 21.5 per cent. It seems, therefore, that the article is not only misnamed, but is found wanting in other respects.

Beef-tea also has long lost prestige as a dietetic. It has hardly any nutritive value. Albumen is the constituent desired from the beef; it contains the nitrogen. But albumen coagulates at 160° F.; boiling beef in water at 212° F. will not extract the albumen; it only serves to lock it up the tighter. No nutritive value, of any consequence, can, therefore, be imparted to the water in which beef is boiled. This water cannot support life. Beef-tea has gone into disrepute along with the extracts and essences: stimulants—little more.

But why cannot a sick man digest meat? Is it not because an impaired stomach refuses to break down the organized fibre, and to set free the albumen? The raw white of an egg is easily assimilated even when milk is rejected. Why not, then, use meat before it is organized at all, viz., blood? Blood is but meat in a liquid form, every ounce containing as much solid matter as an ounce of meat. If digested and assimilated, there is no reason to suppose that it will not feed the tissues in the same manner as beef. Blood was designed by nature as tissue-food.

But it is argued that blood is disgusting to patients, and few will take the prescription. This is admitted; but the same argument holds good with cod-liver oil. Both can be disguised, however. If defibrinated blood be first dried,* afterward it can be dissolved in a suitable vehicle, to render it palatable. Of several such vehicles subjected to experiment, a mixture of brandy and glycerine seems best. One part of each to four parts of water, in which the desiccated blood is first dissolved, furnished a pleasant mixture. The solution can be made of the same strength as the original blood, and is easily tolerated by the stomach. About a drachm of the powder in each fluid ounce of the finished preparation should be employed.

Blood, as an article of diet, has long been used by the Germans in various ways. Patients who drink it at the abattoirs for wasting diseases are frequently greatly benefited by the practice; and at the various hospitals and public institutions in New York, where it is given *per orem*, there is no hesitancy in the expression that benefit accrues from its use.

The article quaffed at the butcher's shambles is always defibrinated. This is accomplished by stirring and then removing the stringy fibrin. The fibrin in this condition, from its resemblance, is called veins by the unscientific butchers. The blood is then ready for drinking, and is said to taste much like warm fresh milk. Such a small amount of nitrogenous constituents is lost by defibrinization that the value of the blood as a nutrient is not materially lessened.

26 West Sixteenth Street.

Medical Legislation.—The State Senate has passed the bills regulating the sale of poisons, and to secure registration in New York City of children born during temporary absence of the parents from that city.

*See article on New Method of Rectal Alimentation, Medical Record, Jan. 3, 1880, for description of desiccated blood.

Progress of Medical Science.

The Influence of Age on the Result of Amputations.—From results obtained under Lister's method at Volkmann's clinic, at Halle, Obert claims to have shown that age has absolutely no influence on the result of amputations, provided that two things can be avoided, viz., septic processes and loss of blood. He believes that the elimination of both these elements of danger is at present easily accomplished. Immunity from septic infection may be invariably secured by a conscientious carrying out of Lister's treatment. Hemorrhage, on the other hand, can be reduced to a minimum by Esmarch's method, and thorough arrest of hemorrhage after removal of the bandage. In corroboration of his views, Obert compares the results of amputations performed on old people (over fifty years of age) with similar operations on others, without reference to age. Both classes of patients were treated by the Lister method. Of 220 individuals operated on since March, 1874, nine, i. e., 4.1 per cent., died. In the 48 cases where the patient had passed the fiftieth year the deaths were two in number, this being equivalent to 4.17 per cent. Hence, the issue as regards life stands in no relation to the age of the person. Of these 48 cases were between 51 and 60 years of age, 13 between 61 and 70, 4 between 71 and 80, and one patient, who recovered after amputation of the thigh, was 84 years old. As regards the extremities involved in these cases, he gives the following details: 7 amputations of forearm, 6 of the arm, 1 exarticulation of the humerus, 7 partial amputations of the foot, 13 amputations of leg (with 2 deaths), and 14 amputations of the thigh. In one case the fatal issue was determined by the supervention of tetanus. In the only other instance of death there was an incomplete recovery from the effects of the narcosis, the subject being a drunkard. Healing took place in every instance without the slightest reaction. In fifty per cent of the whole number union was effected by an absolutely primary intention; in the remainder healing was delayed by limited marginal gangrene of the flaps, or slight fistulous suppuration.—*Centralblatt fur Chir.*, Jan. 10, 1880.

Adenoma of the Breast.—From a careful study of seventeen cases of this affection, Dr. S. W. Gross, of Philadelphia, dissents from the most accepted definition of adenoma, which describes it as a simple exaggeration of the normal physiological structure of the gland, the only difference being a sparse formation of connective tissue in the morbid growth. He has found but one specimen which approaches this description, and in that the likeness to the normal structure was far from striking, the efforts of nature having been limited to the excessive production of glandular apparatus, without attempting to unite the acini into distinct lobules attached to excretory ducts. The remaining sixteen examples all showed either marked enlargement of the acini, or offshoots from the dilated and cystic acini, in the form of tubes or ducts, with aberrations in the character of their investing epithelium. Thus, in ten instances, the tumor was composed of excessively dilated acini packed with polymorphous cells, which could be expressed from the cut surfaces of the growths, as atheromatous moulds or plugs. In the other six specimens the ducts predominated, and these arose, as he demonstrated in a paper published in the *American Journal of Medical Sciences* for October, 1879, from the dilated acini by a process of budding and extension into the scant connective tissue of the gland. In these cystic tubular adenomas, the epithelium, instead of being polyhedral, assumes a cylindrical or columnar form. Hence, he concludes, true adenoma consists not only in a disorderly hyperplasia of the lacteal glands, but also in deviations of the form, size, and arrangement of the epithelium, on which account it is atypical in the strict sense of that term. It is characterized by its firm consistence, nodular outline, slow and equable growth; its occurrence in child bearing females toward the thirty-fifth year; limited discoloration and adhesion of the skin, with ulceration late in the disease, and freedom from retraction of the nipple; prominence of the subcutaneous veins, attachment to the chest, and involvement of the axillary lymphatic glands. If the tumor has been preceded by a discharge from the nipple, the probabilities in favor of its being an adenoma are greatly increased. Adenoma evinces a decided tendency to recur, but there is no evidence going to show that it infects distant organs.—*Philadelphia Medical Times*, Jan. 31, 1880.

Acute Joint Affections in Diphtheria.—Dr. E. A. Kelley, of Waterford, Ohio, reports two cases of acute affection of the large joints occurring during the course of diphtheria. The first made its appearance on the tenth day of a mild attack of diphtheria, and was characterized by a tense and painful swelling of the joints, moist skin, with occasional profuse perspiration at night; temp., 101° F.; pulse, 100. The second case differed only in its appearance on the fourth day of the disease, and an evening temperature of 102° F. In neither case was there any actual paralysis; in each, voluntary motion was restrained on account of the ensuing excruciating pain. The enlargement was not a simple passive œdema, but plainly inflammatory. It displayed, besides pain, heat, redness, and swelling, marked hyperæsthesia and a local, minute, papilliform eruption. In each the knees and shoulder-joints were the most acutely attacked. The radio-carpal and tibio-tarsal articulations were but slightly involved; the distal small joints not at all. The diphtheritic process, although moderate, was distinctly marked in each. They were treated with an alterative at bedtime, followed by a brisk saline in the morning; sedatives to control pain and procure rest, and a cooling diuretic; with, in one case, full doses of the tincture of the chloride of iron, and in the other, quinine. A rapid diminution of the symptoms ensued, and they entirely disappeared on the fourth day, a speedy convalescence following.—*Cincinnati Lancet and Clinic*, Jan. 31, 1880.

Concussion of the Spine.—At a recent meeting of the Boston Society for Medical Improvement, Dr. R. M. Hodges read a paper on "So-called Concussion of the Spine," the purpose of which was to show that we have no knowledge justifying the proposition that what is called "concussion of the spine" is due to a molecular disarrangement of the substance of the cord by an assumed shake or jar; that vascular disturbances (anæmia, hyperæmia, hemorrhages, spinal apoplexy), followed by meningitis, myelitis, or degenerative changes of the spinal cord, are shown by pathological as well as physiological histology, by experimental pathology, and, to a certain extent, by post-mortem examinations, to be the true cause of symptoms hitherto commonly designated as "concussion of the spine;" that, in spite of hysteria and exaggerated and fraudulent manifestations frequently

accompanying these cases, the reality, if not the precise character, of any existing spinal lesion can almost always be recognized by objective and demonstrable symptoms; that the prognosis of this class of spinal injuries in severe, as well as slight instances, is far more favorable than is usually supposed; that, as a plea in suits for damages, "concussion of the spine" does not, and is not entitled to have the weight and importance usually attached to it; that erroneous impressions in regard to the severity of this injury, prevalent in this country as well as in England, have been fostered by Mr. Erichsen's book on "Concussion and Nervous Shock," which presents an exaggerated picture of its symptoms and consequences, not justified by our present knowledge of the subject.

In the discussion which followed the reading of this paper, exception was taken to the assertion of the unmistakable nature of the objective phenomena. Dr. Cheever could recall but two cases in which this was true. In one there was paralysis agitans, which could not be assumed; in the other there was mottling of the skin, caused by minute capillary congestions, and due to true vaso-motor paralysis. Dr. Putnam did not think that definite lesions, such as might eventually cause myelitis, would necessarily reveal themselves by definite symptoms in the early stages of the case, and called attention in this connection to the experiments of Duret and others upon concussion of the brain. The setting aside of the term "concussion of the spinal cord" as having no definite significance was opposed by Dr. T. B. Curtis. He considered it a clinical designation, applying to certain etiological conditions; and, as such, is appropriately used when an individual has been subjected to an external violence which may have left no physical signs of injury, but which, as we know by experience, involves a liability to the subsequent development of grave secondary affections of the spinal cord—namely, myelitis, meningitis, and sclerosis. The symptoms to be observed are mainly the well-known and unequivocal symptoms of myelitis, followed by ascending and descending sclerosis. Of these, some, as the disturbances of mobility and sensibility, are subjective and therefore capable of exaggeration and simulation; others, consisting principally of trophic disturbances, are objective. The prognosis in these cases, Dr. Curtis is disposed to think, is not as unfavorable as is usually supposed. Recoveries from myelitis, meningitis, and sclerosis, with long-standing paraplegia, followed by spasmodic retraction of the legs, are by no means rare. In conclusion, he proposes a new definition of spinal concussion. The term should denote a condition resulting from external violence, in which the patient is liable to be affected with certain definite and recognizable secondary diseases of the spinal cord, namely, myelitis, meningitis, and sclerosis.—*Boston Medical and Surgical Journal*, Feb. 5, 1880.

The Night-Sweats of Phthisis.—Dr. Köhnhorn reports two cases which had resisted the successive employment of quinine, atropia, digitalis, boletus caricis, folia salviæ, and various external lavements, frictions, inunctions, etc. These cases were quickly cured by the external application of a powder prepared after the following formula:

℞. Acid salicyl..... (3.0) gr. 48
Amyl..... (10.0) ʒ iiss.
Talc earth..... (87.0) ʒ iij.
M. F. pulv.

The entire surface of the body is powdered over with this preparation. To avoid the excitation of coughing by the salicylic acid, patients are directed to apply a handkerchief to the nose and mouth during its application. The same powder has been employed in the army for the treatment of hyperidrosis of the feet.—*Berl. klin. Woch.*, No. 1, 1880. *Allg. med. Cent.-Zeit.*, Jan. 10, 1880.

A New Instrument for Mechanical Compression of the Testicle.—The difficulty of obtaining and maintaining equable compression of the testicle has been recognized by all surgeons. To obviate the disadvantages of adhesive strapping and rubber bandages, Dr. Octavius A. White, of this city, has devised a new mechanical appliance. It consists of a very light shell of hard rubber, moulded so as to receive within its cavity the swollen testicle and its scrotal coverings. About one-third of the upper portion is bevelled off, this shape being found, by experience, to afford the best mechanical support to the pendulous organ. A cleft runs down the front of the shield, which permits free overlapping of the thin edges, thus making ample provision for all necessary reinforcement of compression which may be required during the management of the case. The edge surrounding the neck of the tumor is everted to prevent cutting. In applying the instrument, it is desirable that there should be a certain amount of local depletion, which may be obtained by a short rest in the recumbent posture. A shield of the proper size is then fitted to the affected organ, and a narrow roll or bandage is passed around the upper part of the instrument, to prevent the testicle from slipping upward out of the shell during the succeeding manipulation, which consists simply of tightening the lacing strings connecting the two free edges made by the cleft described above. The prominent features of this scrotal shield, support, and compressor, are its remarkable lightness, the weight not exceeding eight grammes; great readiness and facility of application; complete command afforded the surgeon over the degree and duration of direct pressure to the testicle; firmness and general diffusion of the pressure; entire painlessness attending and during its application and removal, even though the scrotal sac be well covered by hair; and finally, perfect cleanliness, the fixture being easily taken off and washed. Among the diseases in which the continued use of this instrument has been productive of speedy and highly satisfactory results, are mentioned varicocele and neuralgia of the testis. The instrument is manufactured by G. Tiemann & Co., of this city.—*Boston Medical and Surgical Journal*, Jan. 29, 1880.

Abnormally High Temperatures.—The case reported in 1875, by Mr. John W. Teale, in which, subsequent to severe spinal injury, the temperature for sixty days ranged between 108° F. and 122° F. (*see* Vol. 10, Medical Record, page 270), has been received with so much scepticism by scientific men in London, that, in a recent paper on this subject, by Dr. Donkin, no mention of it is made. This induced Mr. Teale to reaffirm the correctness of his observations, and he states that this patient, during a relapse, came under the care of Mr. Hind, of Stockton, who, on one occasion, found the heat in the axilla so great that the mercury broke the tube at the top of the instrument. Dr. Donkin's interesting series of cases is claimed as strong corroborative proof by Mr. Teale, who thinks the following points fully established: 1. Temperatures above the degree formerly supposed to be necessarily fatal, do

sometimes occur without a fatal issue, may even with great extreme peril to life. 2. Such exceptional and excessive temperatures, as a rule, end in recovery. 3. The conditions of body in these cases appear to be distinct from the conditions existing in fevers, in which the rule as to the extreme peril of temperatures of 107° and upward remains unassailed.—*The British Medical Journal*, Jan. 24, 1880.

ACUTE MUSCULAR ATROPHY.—At a recent clinical lecture at the Jefferson Medical College Hospital, Dr. Bartholow presented a typical case of this disease, which was associated with syphilis. But little relief can be hoped for, except, as in this case, where the disease was due to a specific cause. When the wasting is far advanced, the curability of the case can be determined by the electric contractility of the muscles. So long as the stimulation of electricity elicits response there is hopes that sufficient muscular tissue is left to afford some good result, if proper treatment be employed. In this connection it is well to bear in mind that the muscles may respond to a slowly interrupted galvanic current, when they would be unaffected by a faradic current.—*The Clinical Notes*, Feb. 7, 1880.

EPITHELIOMA OF THE CERVIX UTERI.—The advantages to be gained from such an instrument as Paequelin's thermo-cautery, in operations for epithelioma and other cancerous affections of the uterus, have been limited by the difficulty experienced in protecting the vagina and vulva from the heated shank of the knife. When a wooden sheath is used the wood may be ignited and the patient badly burned. The use of wet cloths give rise to so much steam as to obscure the view, and besides, the protection afforded is very incomplete. Asbestos answers well for about three minutes, when it becomes hot and useless. To obviate these difficulties Dr. Wilson, of Baltimore, has devised a hollow metallic shield through which a constant stream of cold water flows. This protector is said to answer the purpose admirably, the soft parts being perfectly guarded from the effects of the heat, while the knife itself is capable of being raised to any desired temperature. Owing to the difference in the length and construction of the different knife-shanks, it is found necessary to have more than one of "Wilson's anti-thermic shields" for each set of knives. For the blunt cautery a hinged shield has been made, which necessitates a separate water-supply for each side. All this difficulty may be readily avoided by a slight modification of the shafts of the knives and canteries, which will not in any way impair their usefulness. The advantages of Paequelin's instrument over the electro-cautery, it is claimed, are not only its greater cheapness, portability, and reliability, but also its greater effectiveness, it being possible to advance farther and more safely into the uterus and the walls of the vagina with this than with the electric wire. The absence of hemorrhage and the complete removal of all septic material, the closure of the divided vessels, thus preventing the absorption of septic germs, are its advantages over all cutting instruments.

SURGICAL STATISTICS WITH AND WITHOUT LISTERISM.—The statistics given by Mr. Lister of the results from his operations performed under strict antiseptic precautions, have called forth a reply from the pen of Mr. James Spence, of Edinburgh. Mr. Lister took a period of five and three-quarter years, during the period when he says his antiseptic system has been more perfectly carried out. During that time he had performed eighty major amputations, with nine deaths. Claiming the same right, Mr Spence takes a period before the antiseptic system was heard of, when he used the very simplest dressings. He finds that out of sixty three major amputations he had three deaths, during the same period, out of twenty three excisions there was but one death. Mr Spence objects to Mr Lister's elimination of fatal cases, by which means the claim is made that "no patient died from a preventable disease," and he reminds Mr. Lister of a fatal case of amputation at the shoulder joint, of which no mention had been made. Mr. Lister's experience in mounted fractures of the femur is thought to be unusually extensive, for during a much longer period Mr. Spence has met with but two such cases, and one of these was rather a case of delayed union than non-union. Both were operated upon successfully, and without giving rise to constitutional symptoms. According to Mr. Spence, Mr. Lister does not state clearly the results of his operations as regards union, but Mr. Spence knows of one case in which the operation was repeated once or twice without union resulting. Of the resection of bones during acute necrosis, Mr Lister gives no examples; in this class of cases Mr Spence has been uniformly successful, and no spray or special antiseptic method has been used. Nor does Mr Lister give his results in excision of tumors, although Mr Spence claims that the large cut surface exposed to the air during these operations render this class of cases, according to the germ theory, especially liable to infection; in Mr. Spence's experience it is the exception for these cases not to do well. In regard to the application of the antiseptic system to chronic abscesses, Mr. Lister is asked to explain the fact that when he left the Edinburgh Infirmary there remained in his wards, uncured, some seventeen of these cases. Mr. Spence found in his experience that, as regards constitutional symptoms, these case did well under the antiseptic system, but not as to cure or arrest of discharge.—*The British Medical Journal*, Jan. 24, 1880.

CASE OF DILATATION OF THE STOMACH SUCCESSFULLY TREATED BY THE SYPHON STOMACH-TUBE.—The topical treatment of certain diseases of the stomach, when accompanied by obstinate vomiting, as first suggested by Kussmaul and Leube in Germany, is illustrated by a successful case which occurred in the practice of Dr. W. Sweddin, of Bath. The patient, aged forty-eight, during an attack of scarlatina in 1854, had complained of a pain in the stomach, which was confined to a small spot about the size of the end of one's finger, and was accompanied by general dyspeptic symptoms. Some time in 1855, or a year after the first symptoms made their appearance, he began to vomit, and did so several times a day for many months in succession. He was incapacitated from working each year, for a period extending from eight weeks to eight months. Various drugs had been employed, among others bismuth, both in solid and liquid form, strychnia and iron, citrate of magnesia, etc., each of which only gave him temporary relief. When seen in April, 1879, there were distinct evidences of dilatation of the stomach. He vomited several times every other day, often as much as a basinful at a time, and it was so sour that it felt as if "it would take the skin off his mouth." The vomited matter commenced to ferment if allowed to stand for a short time, and when a small quantity of bicarbonate of soda was added, active effervescence would take place. The bowels were so much constipated that it was often necessary

to use enemata. The pain was worse over the hypochondriac and inguinal regions, and sometimes, worst of all, over the lower dorsal vertebræ. He was unable to work. The treatment with the syphon stomach-tube was commenced on April 30th. The instrument employed was a gum-elastic tube from the ordinary bivalve stomach-pump. Retching was at first caused by the introduction of the tube, and a pint of sour turbid fluid flowed through the syphon, which felt very hot. A solution of carbonate of soda (3 i. to Oi.) was then injected into the organ. On the next day there was marked improvement, and when the instrument was introduced there was not so much tendency to vomit as before. Up to May 16th the tube was employed daily; he had been quite free from pain for over a week, and felt much better than at any time for the previous six months. The tube was introduced for a period extending over a little more than two months, sometimes every other day, and later every third day. At the end of that time he felt quite well and was able to resume work.—*British Medical Journal*, Jan. 10, 1880.

Japanese River or Flood Fever.—A new disease is said to prevail in the months of July and August in the flooded districts of Japan, and is claimed to be acute and infectious, but not contagious. The period of incubation lasts from four to seven days, generally manifesting itself on the sixth after coming to an infected region, or handling hemp brought from there. The first symptom is a severe rigor, followed by fever; these symptoms return in the course of the day, and are accompanied with headache, throbbing of the temples, loss of appetite, and extreme prostration. On the second day the characteristic symptom makes its appearance—viz., tenderness of either the inguinal, axillary, or cervical lymphatic glands. A dusky spot covered with a dry scale or scab, will be found at the periphery of the region in which the affected glands are situated, and this is pathognomonic of the disease. The face is red while in the recumbent position, pale when erect. The patients continually whimper throughout the disease, and they have an intense horror of the slightest breath of air, or of a drop of water being brought in contact with their skin. The pulse is 80 in men, 100 in women, and the temperature varies from 101° to 103° F. Where the skin is moist there is a small, round, blackish spot, with a slight depression in the centre; it has a well-defined margin, the adjacent surface being soft and livid red. The tissues in the neighborhood are not raised or tender. In a few days the crust can be removed and a round crater-like ulcer is left, having at its bottom a tough, fatty mass. The glands are swollen, but no distinctly inflamed lymphatics can be made out. There is generally catarrhal conjunctivitis—also cough with catarrhal râles. No throat lesions are present. The spleen is enlarged; no albumen in the urine, and the bowels are constipated. Fever is continuous, and increases; on the evening of the fifth or sixth day being 104°. The eruption makes its appearance on the sixth or seventh day, accompanied by an increase of fever and restlessness. The exanthem is first seen on the temples and cheeks as large, flat papules of dark red color, with smaller lichenous spots between, resembling measles. The forearms, legs, and back are next affected, the thighs and arms are very indistinctly marked, and the throat and neck generally remain free. The eruption lasts from four to seven days, sometimes only one. The disease is now at its height, and there is often delirium at night, deafness, dry lips and tongue. The ulcer suppurates. About the end of the second week remissions occur, diarrhœa supervenes, and convalescence takes place. Fatal cases are accompanied with high fever, copious bloody stools, coma, mania, failure of the heart's action, and œdema of the lungs. About eight per cent. of those living in the affected districts have the disease, and the mortality is about fifteen per cent.—*Lancet*, Jan. 10, 1880.

On the Origin of Tetanus.—In an investigation of this subject which has received but comparatively little attention, Surgeon-Major J. J. L. Ratton, of Madras, says that the group of symptoms known as tetanus is produced by peripheral nerve-irritation. This fact is shown by the morbid anatomy of the disease, and also that when treatment is directed toward the removal of this phenomenon, a cure is effected unless the lesions have existed for too long a time. To show that the disease is caused by peripheral nerve-irritation, cases are mentioned, one where a rusty nail, piercing the foot of a midshipman, produced all the symptoms of acute tetanus, and which was relieved by division of the posterior tibial nerve. Another case is cited in which injury to the supraorbital nerve produced all the symptoms of the disease, and division of that nerve effected a cure. As to the cases of so-called idiopathic tetanus, they are either the result of worms, or are due to puerperal or menstrual troubles in which the peripheral nerves are irritated. It is also shown that the symptoms of tetanus are those of constant irritation of the excito-motor system, with great exaltation of the reflex function of the cord and medulla, and that the spasms are brought on by the slightest stimulus to the peripheral nerves, while the brain is clear and unaffected. The pathological changes found after death fully corroborate the above view held as to the origin of the disease, because the continued nerve-irritation, reacting upon the medulla and causing tonic spasms, would, up to a certain point, give no evidence of morbid change. If, however, the irritation were continued, hyperæmia with molecular changes, and often inflammation would result, and this is what is seen.—*Brain*, Jan. 1880.

The Presence of Fat in the Urine.—In his work on urinary diseases, Dr. Roberts says that the discharge of quantities of liquid fat by the kidneys is so uncommon that its occurrence has been doubted. Dr. Oliver, of Newcastle-upon-Tyne, cites two examples of this rare condition. The first was that of a woman, the subject of fits, epileptiform in character, whose urine, when examined, was found to be milky in appearance, the opacity being increased on heating, and not affected by the addition of nitric acid. After standing for some hours, a gelatinous-looking coagulum, somewhat flocculent at the sides, appeared suspended in the fluid. This, when examined microscopically, was found to consist of fat-globules in great number. There were no tube-casts, and but few epithelial cells and lymphoid corpuscles. The specific gravity was 1014, and reaction acid. The urine was examined at other times, with essentially the same results. The other instance was in a woman troubled with epileptic fits. In this patient, albumen was discovered in the urine at times; but when the report was made, none could be detected, while numbers of fat-globules were present. In each of the patients the appearances presented by the urine were similar to those shown in an examination of milk.—*British Medical Journal*, December 27, 1879.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 13, 1880.

STATE MEDICINE AND THE MEDICAL PROFESSION.

THE unusually large number of bills relating to medical matters, now before Congress and various State legislatures, is an interesting and significant fact. We find that at present, in Congress, there is legislation being asked for the National Board of Health, such as will give it greater power and a wider scope of influence. In addition to this, the Treasury Department is urging the necessity of laws to establish a veterinary sanitary commission; there are also bills to place the Marine Hospital Service on a higher and firmer basis, and to secure physical examination of those who serve on our merchant vessels. The Agricultural Bureau is pressing its claims for money and power with which to do more work in veterinary science; and the State Department is likely to add a medical side to the duties of its foreign officers, obliging them to keep a watch upon the sanitary condition of the ports with which our country is in communication. The subject of inter-State commerce is now being discussed, and has received most serious examination on account of the medical questions that aroused it.

In the States the importance of State and local health boards has already become widely appreciated. Questions, also, of medical registration, medical education, medical charity, and even of proper medical treatment in public institutions, occupy the attention of our law-makers, and, with the various other branches of State medicine, make a very respectable part of the legislator's work.

It is not to be supposed that this past year is so markedly different from all others; but, on looking back no more than ten years, one cannot fail to appreciate a great change and a great progress. The influence of medical men and medical science is extending. It reaches where it has never reached before, and it is rising to a prominence in political and social matters which is now becoming noticeable, and which every physician ought personally to appreciate and understand.

This tendency is one which is both just to our profession and beneficial to the State. The physician is a person who is obliged to undergo a good deal of mental discipline in passing through his ordinary course of study, and his afterwork is of a kind likely to develop all his faculties, strengthen his character, and elevate him morally. He ought, therefore, to be an important factor in society, aside from his therapeutical or purely scientific work. On the other hand, the benefit to society, from having such a class actively engaged for its general welfare, is perfectly apparent.

The statements thus made as to the growing prominence of the medical profession may appear to be at variance with the melancholy facts regarding the over-supply of doctors and the superfœtating characteristics of our medical colleges, to which we have at other times made reference. But it should be remembered that a large part of the evils produced by this over-competition are personal ones. They fall upon the younger members of the profession rather than on the older ones, who represent its character and influence. And, besides this, the fact that the profession is overcrowded carries a certain amount of good with its great evils. The law of the survival of the fittest applies to struggling doctors as well as to the organic kingdom generally, and the larger the number the more intense is the struggle and the greater the success of those who come out ahead. It is an unfortunate fact, to be sure, that the fittest is not always the best, but is liable to be the one who can talk the loudest or advertise with the most discretion. Nevertheless, there must always be something of good as well as of strength in the man who wins a hard race; and, as society grows more intelligent, this good will become a larger and more essential element. In addition to all this, the present surplus of medical practitioners, besides stimulating competitive effort, furnishes many well-trained minds, whose energies the mere compounding of healing mixtures does not wholly absorb. These will naturally desire to have the field occupied by medicine enlarged, and we may expect an impetus to medical statesmanship from them.

Thus it will be seen that this surplus of doctors, although it causes a dangerous rivalry, also prevents any but able men reaching the top, and helps to widen the field in which medical training and knowledge may be applied. The evil is not to be justified in the least, but we can say that it carries enough good with it to negative much of the bad.

It is a fact, at any rate, that there is this tendency "broadly to bourgeon;" and one of the results of it

must be that medical men will take a greater and more active interest in public affairs.

A venerable professor in a college in this city used to tell his students to shun political life. If by this it was meant to shun the life of a politician, the advice was good. But it is neither public-spirited nor wise to advise any class of persons to avoid politics. Certainly doctors should not do so; and if they would pay a little more attention to primaries and the political condition about them, they would not have to complain of the difficulties of securing the legislation they desire, nor would the influence of quacks prevail so much in the councils of our rulers. We hear of a health commissioner in a Western State who is a most unblushing charlatan; the Board of Health of Georgia has collapsed, because the State legislature, in spite of the protests of the profession, would not appropriate the pittance necessary for its running expenses. Other States are cramped by the same ignorance on the part of the public; while the influence of the profession, though growing, is still weak, and, meanwhile, the advertising quack gets rich and influential, rides bravely into our legislative halls, and helps to make laws for the regular practitioner.

We repeat, then, that the profession must, for its own protection, take a more prominent part in public affairs and legislation. State medicine must yet form an important branch of statecraft, and the wider duties which this department of knowledge brings ought to be thoroughly learned and promptly assumed by us. Nothing should be neglected that will give a wider and higher scope to the application of medical science. For there is, after all, a small side to the work of our profession, as well as a great one. There is a certain pettiness in the daily routine of prescribing pills to the bilious and plasters to the rheumatic—a routine that represents a portion of the "services cheerfully rendered to the suffering humanity" of a dispensary class. There is not often much intellectual tension called out in treating an incised wound or ligating a pile. And the absence of any great dignity or intellectuality in this part of our work, useful though it is, is quite keenly appreciated by the laity; so that the average doctor grows gray in an atmosphere of threadbare jokes upon the frailer points in his profession. We will probably never rise entirely above these facetiæ, the sense of humor is so exquisitely lacking in a certain portion of the community. But the feeling that what is good in our profession is becoming better—that its dignity is increasing and its usefulness extending—all this will prove something of a balm if any one is sensitive, and will at any rate furnish assurance and stimulus to all who are in earnest. It will not be many years before the great utility of State medicine will be associated with the idea of the doctor, as closely, perhaps, as is now the potency of pills.

THE ANTI-VIVISECTION ENTERPRISE.

In our last issue we mentioned the adverse report of the Assembly Committee on the bill introduced some weeks ago, at the instance of Mr. Bergh, to prohibit vivisection in medical investigations. This disposes of the most determined and unreasonable attack which has been made in this country for some years upon the experimental element in medical progress. The bill was a very short one, but could hardly have been more stringent or more comprehensive. It consisted only of three sections, the first of which declared that any act of vivisection "performed upon any living animal" should constitute a misdemeanor; while the second defined the term vivisection as including "every investigation, experiment, or demonstration producing, *or of a nature to produce*, pain or disease in any living animal;" and the third provided that the proposed act should take effect immediately. It was accompanied by a memorial from Mr. Bergh, in which he informed the Legislature that experiments of this kind were without any practical or beneficial result; that they were demoralizing both to the medical men and the students; and that they had been the subject of "universal condemnation by the more eminent members of the medical profession in Europe." The bill was presented, at Mr. Bergh's request, on January 21st, in the Senate by Hon. Robert H. Strahan, and in the Assembly by Hon. Edward Mitchell, and was referred in both houses to the Judiciary Committee. Afterward Mr. Bergh was granted a hearing on the subject before a meeting of the joint committees in the Assembly Chamber, with every allowance for oratorical display and pictorial illustration of what he calls the "atrocities of the dissecting-room." It cannot be said that he was hampered or obstructed in any way in his attempt to urge upon the Legislature the passage of the bill.

On the other hand, the medical profession were not idle. To them the subject is so familiar, and the value of experiments on animals is so fully demonstrated by the experience of centuries, that it seems almost a work of supererogation to expose the sophistries and misrepresentations of the anti-vivisection reformers; but it becomes a necessity to do so, when the matter is thrust upon the attention of the Legislature. The State Medical Society took action upon the subject at its annual meeting in February, and appointed a permanent committee to take charge of the interests of medical progress which were threatened by the bill. All the principal medical societies in the State united in a memorial to the Legislature remonstrating against the proposed law, and a similar remonstrance was prepared by the medical colleges. These two memorials, which were printed in full in our issue of February 28th, were presented to the Legislature by the Hon. Mr. Mitchell, on February 20th; and the profession were

also accorded the privilege, as was right and proper, of appearing before the joint committee in opposition to the views presented by Mr Burgh. The matter seems to have had a complete ventilation, so far as the Legislature is concerned, and the result was that on the 27th of February the Judiciary Committee of the Assembly reported the bill adversely, and the Assembly at once agreed to the report with only a single dissenting voice. We understand that the Committee were unanimous in their opinion against the bill. The Hon. Mr. Mitchell, by whom it was introduced, finally moved in the Committee to report against it, and also moved in the Assembly to accept the adverse report. The Senate Committee have as yet made no report, and, very likely, will not make any; but it is understood that their opinion is equally decided against the bill. This attempt to abolish the experimental method in medical science has therefore met with the failure which it deserves.

COMPULSORY REGISTRATION OF INFECTIOUS DISEASES.

Efforts to secure the passage of laws compelling the registration of infectious diseases have been made by the British Medical Association, and its work has already met with considerable success. Parliamentary powers have been obtained by fifteen towns in England and Scotland, obliging notification to the proper authorities of infectious diseases as soon as they occur.

Such compulsory notification exists in this country wherever we have city health boards. In most cases, also, the diseases are registered, the record being regularly published. In this respect we are ahead of the British cities.

In two particulars, however, their laws are the better. Thus, in England and Scotland, the notification of infectious diseases is made compulsory on the occupier or person having the management or control of the building in which the disease occurs. The doctor has only to certify to the existence of the disease and then hand the paper over to the householder. For this he is paid from fifty to seventy-five cents. With us, the doctor not only has the responsibility of filling up and forwarding the certificate, but he receives no remuneration for his work. This is not just, and although it is not a very great matter, we do not believe that medical men should be imposed upon unnecessarily in any case. Let them take concerted action upon the subject and the remedy could probably be obtained.

SUSPENDED ANIMATION AND THE HIBERNATION OF ANIMALS.

Not long ago an article appeared in an Australian journal describing a process by which animals could be frozen and kept alive indefinitely in this condition; when the proper time arrived they could be brought to life and then killed for food. A large establishment for the consuming sheep and pigs, and then transporting them to England, was declared to have been erected, and the details of the work were described with great care and minuteness. The animals were first curarized and then frozen solid. When they were to be revived a preparation of the root of the "[illegible]" was injected into the veins, warmth was gradually applied, until the normal temperature was reached, and then by artificial respiration the functions of life were restored, and the lambs and pigs skipped about with all the liveliness of their auto-glacial condition. The story was a hoax, but it was a very clever one, and had so much of scientific truth worked in with it, that some very cautious journals at first indorsed it as true.

The idea of being able to accomplish anything like a prolonged suspension, almost complete, of life in warm blooded animals, rests chiefly upon the known facts of hibernation. A total suspension of vital functions has been accomplished, in all probability, in cold-blooded animals, as in well-attested cases where fish have been frozen and then thawed out and brought to life again. It cannot, perhaps, be absolutely denied that there are conditions under which warm-blooded animals may be treated in the same way. It is a fact, at any rate, that a very great lowering, an almost complete suspension of vital action, is part of the physiological history of some animals. And, according to Dr. B. W. Richardson, if the muscular and nervous irritability could be gradually and synchronously reduced, a condition might finally be reached, in all animals, so nearly resembling a total suspension of life as to be practically undistinguishable from it. The nearest approach to such a condition, however, now known, is the phenomena of hibernation.

Hibernation is, in most respects, only an exaggeration of the physiological condition of sleep, and is appropriately called by the Germans the winter-sleep or summer-sleep of animals. It is most frequently seen in the rodents, especially the bat, marmot, and hedge-hog. We find it, however, in more highly developed animals, as well as in many reptiles. It is not the torpor which comes from cold; indeed, in the tropics, the process often occurs in summer. It is rather a provision of nature, by which the animal is enabled to bridge over seasons when there is no food to be had. Or, to speak more nearly in accordance with Darwinian data, it is a condition brought about by the gradual adaptation of the animal to a foodless environment. In this state, in the bat, for instance, the respiration almost entirely ceases, and only venous blood circulates through the system; the heart beats but fifteen times in a minute, the temperature sinks till it is only two or three degrees above the surrounding atmosphere, and excretion nearly ceases. According to Marshall Hall, who

studied the subject with great care, the muscular irritability is increased in proportion as the other vital functions are lowered. This he considered to be the peculiar fact which allowed life to continue, for the venous blood, passing through the heart, would not be sufficient to irritate it to contractions were its muscular tissue not abnormally sensitive. This does not represent the whole truth, however, since it is now known that a heart contracts, other things being equal, in proportion as it is well nourished. With the slight nourishment furnished it by the venous blood, its contractile efforts would naturally be lowered. During the long periods of hibernation into which some animals enter, the system must supply its very small requirements from the excess of tissue, particularly the adipose, which it had previously accumulated. It is asserted that in bears the weight after hibernation is not greatly diminished. This, however, if true, only proves to how low an ebb the vital actions sink.

It is assumed that if hibernation is possible in the highly-developed of the lower animals, it may be sometimes induced artificially, or by disease, in man. The former possibility has been lately claimed by a, possibly hypothetical, Dr. Tanner, in the public newspapers. He offered to prove, by actual experiment in this city, that he can live for thirty days without food. We know that in certain neurotic diseases patients exist for a long time on extremely small quantities of food. In cataleptic conditions there is occasionally a general lowering of the systemic activity, which corresponds, in some respects, to the condition of hibernation. In no case, however, so far as we are aware, have the phenomena of almost total suspension of respiration, of extreme slowing and weakening of the heart, and of lowering of the body temperature to only a few degrees above that of the surrounding air, been combined. Therefore, we may say that as yet, in man, only a partial imitation of hibernation has been accomplished, either by act of will, by force of disease, or by use of drugs.

We may logically infer, moreover, that, as man has never had an environment necessitating hibernation, neither has he now the power of entering such a state. This power in the bear, for example, has been the result of long ages of survival of the fittest. There are no grounds, therefore, for believing in those who claim hibernating powers, whether they be fasting girls or quasi-scientists.

In saying this we refer, of course, to that complete form of hibernation which characterizes the bat, the marmot, and like animals. Hibernation, as we have stated, differs from sleep chiefly in degree, and not in kind; therefore, man does approach the condition slightly every day. Some persons may also have the power to carry the process very far and even simulate complete hibernation as regards certain functions; but that they can imitate it in every respect is theoretically improbable and practically unproved.

As far as the production of so-called suspended animation in other non-hibernating, warm-blooded animals, is concerned, the question stands the same as with man. Here, however, experiment may be tried, and the field is perhaps a legitimate one.

THE CONTRACT SYSTEM IN KANSAS.

THE Kansas laws give the contract for medical care of its paupers to the lowest competent bidder. It is now proposed that the bid shall include the medicines also. The *Kansas Medical Index* very justly protests against such an arrangement. The contract-doctor system is bad enough of itself. In places where there is any competition, the contracts go for a miserable sum; patients become neglected, and the doctors overworked, impoverished, and demoralized. Such has been the result in Ireland; and the danger of such a result is present everywhere that the system is introduced. It is, of course, still worse when the drugs have to be supplied by the doctor. The temptation to use cheap articles must be almost irresistible; and although doctors are, of course, better than any other class of men, they are still human. The *Index* is on the right track, and we hope it may be successful in preventing the adoption of an unjust and dangerous measure.

Reviews and Notices of Books.

BRAIN-WORK AND OVERWORK. By H. C. WOOD, M.D., Clinical Professor of Nervous Diseases in the University of Pennsylvania; Member of the National Academy of Sciences, etc., etc. American Health Primer No. 10. Philadelphia: Presley Blakiston. 1880. 12mo, pp. 126.

THIS little book is quite a readable and instructive one on the subject indicated by its title. It abounds in practical suggestions addressed to the general reader. To the physician it presents no novelty. We are pleased to observe the entire absence of the preaching tendency, so frequently noted in works of this character. The author judiciously abstains from drawing an exaggerated picture of remote possibilities of hygienic neglect. He simply indicates probable results of unnatural modes of life. The reader is warned not to be heedless of the premonitory symptoms of nervous breakdown. The great danger of neglecting these seemingly trivial, early signs, is clearly exposed, and aptly illustrated. We would recommend the careful reading of this little volume to brain-workers in every department of human enterprise. The ambitious student, the straining business man, and the hard-worked teacher, will each in turn derive both pleasure and profit from a perusal of its pages.

NASO-PHARYNGEAL POLYPI. By R. P. LINCOLN, M.D., of New York city. St. Louis. 1879. 18mo.

THIS is a reprint of some interesting cases illustrating the above subject.

ANNUAL REPORT OF THE SUPERVISING SURGEON GENERAL OF THE MARINE HOSPITAL SERVICE OF THE UNITED STATES, FOR THE FISCAL YEARS 1878, 1879.

The principal facts in this report have already received notice. We find several papers of interest, contributed by surgeons of the service. Among the latter are "A Sanitary and Consolidated Sick Report of Chelsea Hospital," covering twenty years, by Surgeon-General Hamilton; also, "Notes from the Cruise of the Revenue Steamer 'Rush' in Alaskan Waters in 1879," by Assistant Surgeon Robert White. These notes show careful observation and industrious study of the sanitary condition and prevalent diseases of the Alaskans. Much that is new and interesting upon the above points is furnished.

MALARIA AND ITS EFFECTS. By J. W. YOUNGE, M.D. Fort Wayne, Ind. 1880.

In an essay of twenty two pages, Dr. Younge discusses the pathology and treatment of malarial poisoning. He argues against the germ theory, and declares malaria as an element derived from marsh-infection, existing under a gaseous form, and exclusively of telluric origin. The different types of intermittent, remittent, and yellow fever depend upon an absorption of this same malarial poison. Dr. Y. is also inclined to ascribe the plague to the same cause. Apart from the theories, the pamphlet contains some interesting facts.

EIGHTH ANNUAL REPORT OF THE NEW YORK FREE DISPENSARY FOR SICK CHILDREN, FOR THE YEAR 1879.

This report shows that 2,936 infants and children have been treated gratuitously during the past year, at a cost of only $1,447.89, the entire expense of the institution.

A PROTEST AGAINST MEDDLESOME MIDWIFERY. By H. GIBBONS, SR., M.D.

This pamphlet, originally read before the San Francisco County Medical Society, embodies a very vigorous protest against the indiscriminate use of the forceps. Dr. G. thinks that, if the use of the forceps was suspended for a year, the list of puerperal casualties would not be increased.

PACQUELIN'S THERMO-CAUTERY, WITH WILSON'S ANTI-THERMIC SHIELD, IN EPITHELIOMA OF THE CERVIX UTERI. By H. P. C. WILSON, M.D. Baltimore, Md.

In this reprint Dr. Wilson describes this anti-thermic shield, which he uses with Pacquelin's thermo-cautery. It consists of a double cylinder, between whose walls water is kept running. It is particularly useful in malignant disease of the uterus and vagina.

A POINT IN HOSPITAL MANAGEMENT. By J. S. PRONT, M.D.

When retiring from the presidency of the Kings County Medical Society, Dr. Pront made an address, of which the present pamphlet is a part. The point advocated is that private patients at hospitals should be allowed to select their own physicians, whether on the visiting staff or not. In this case they should pay him the regular fee.

THE RELATIONS OF CARDIAC HYPERTROPHY TO RENAL DISEASE. By ROBERT SAUNBY, M.D. Birmingham: Hall & English. 1880.

This question is reviewed very exhaustively by Dr. Saunby in the above reprint. He concludes, (1) that in Bright's disease an augmentation of the cardiac hypertrophy is compensatory to the renal defect; digitalis is therefore indicated, and the skin and bowels should be kept active; (2) that the high tension pulse indicates a high degree of toxæmia and relative failure of the kidneys.

SANITARY ORGANIZATION OF NATIONS. By HENRY I. BOWDITCH, M.D.

This is one of Dr. Bowditch's best contributions to sanitary literature. Most of the points made have already been referred to in this journal.

POSTURE IN THE TREATMENT OF INTESTINAL COLIC AND ILEUS. By FRANK H. HAMILTON, M.D.

Dr. HAMILTON considers intestinal colic to be often due to a distention of the intestines with gas, this distention twisting and displacing the gut. He has found that elevating the hips of the patient will, in some cases, bring immediate and complete relief.

Reports of Societies.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, Dec. 20, 1879.

DR. H. B. SANDS, PRESIDENT, IN THE CHAIR.

HYDRO-NEPHROSIS—OPERATION—RECOVERY.

Dr. ROBT. F. WEIR presented a patient who had been the subject of hydro-nephrosis. A young man, æt. 21 years, in July, 1878, was seized with cramps in his bowels. There was no definite history of renal colic, no discharge of bloody urine, retraction of the testicle, etc.; but soon after he noticed a slight swelling in the left iliac region, and could feel a small lump. He was admitted to the hospital November 1, 1878, when the tumor was found extending well up the side. It was aspirated and *two ounces* of limpid fluid were drawn off, which had a specific gravity of 1012. It was examined microscopically: no hooks of the echinococcus were found, nor was urea found by chemical examination. A few weeks subsequently a second aspiration was made, *twelve ounces* of limpid fluid were obtained, but it contained no urea. On December 20, 1878, the tumor having increased to a considerable size, an incision was made in the loin as for lumbo-colotomy. A tumor was soon reached, which, from its peculiar color and appearance, was recognized as kidney, and, on being punctured to a depth of about one-fourth of an inch, a cavity was opened that discharged a semi-translucent fluid freely. A drainage-tube was inserted, and its outer extremity made to communicate with an india-rubber bag filled with carbolized sponges covered with carbolized jute.

The day following the operation he passed a flexible metallic probe, thinking that he possibly might find a calculus in the ureter. It was introduced to the distance of about nine inches, and, deducting the distance to the kidney, entered the ureter to the depth of six and a half inches, but no foreign substance was encountered, although the probe would not go any farther. A French conical bougie was then introduced, and went two inches farther, when it was grasped, as though it had entered a stricture. The patient remained in the hospital, without notable change, until March 1, 1879, when he went out, but returned in April, when the drainage-tube was removed and the wound permitted to close.

It was noticed, as soon as the opening in the loin

losed, that he passed urine in larger quantities hrough the natural passage. Dr. Weir opened the ulging cicatrix, and two or three ounces of clear fluid, with a small quantity of pus, were discharged. After that three abscesses formed in the loin, and the discharge from each one was decidedly more purulent than that from the one by which it was preceded. About the middle of July the wound closed entirely, and since that date the patient had had no trouble whatever referable to the urinary apparatus, and no trace of the tumor could be found by abdominal exploration. Immediately after the operation, which removed the tension, the fluid that was discharged—eight to twelve ounces daily—contained decided evidence of urea, and its specific gravity was considerably higher than that of the fluid drawn by aspiration. There had been no discharge from the loin since June last. Had he recognized a calculus in the ureter he should have proposed two plans of treatment: 1. If it was found in the upper portion of the ureter, to crowd it up, and cut down and remove it; or, 2, if found in the lower portion of the ureter, to pass the hand into the bowel and squeeze it along the ureter into the bladder.

The operation and the dressings were made under the antiseptic spray; and, at first, the contents of the rubber-bag were changed two or three times a day. Antiseptic precautions were observed during nearly his entire stay in the hospital. At no time was there any marked rise in temperature. No hemorrhage occurred when the kidney was opened, and he further remarked that he had cut into the substance of the kidney twice, and no hemorrhage whatever had followed. With regard to hemorrhage, however, he thought the amount depended upon where and how extensive an incision was made.

Dr. Lange referred to his case of pyo-nephrosis, in which the patient was wearing the rubber tube, and the discharge was not more than two tablespoonfuls daily. Her general condition was very good. The opposite kidney was very much increased in size. In his case there was a very alarming hemorrhage when the tissue of the kidney was cut. In a future case, if kidney tissue remained, he should use the galvano-cautery knife in making the opening into the sac. The incision which he made was several inches long, and the kidney tissue was about half an inch thick. The application of ice-water and liquor ferri subsulphatis failed to control the hemorrhage, and it was finally arrested by pressure.

Dr. Weir referred to another case of hydro-nephrosis occuring in a middle-aged woman, who fifteen years ago was attacked by pain in the right hypogastric region, followed by the development of a tumor which gradually increased in size until quite a large swelling could be recognized, and then suddenly disappeared. The physician who brought the patient to Dr. Weir told him that, the night before, the tumor was larger than it had been at any time, but during the night it disappeared and the patient passed a large quantity of water before morning. On questioning the patient, it was found that she had noticed the recumbent posture favored a free discharge of urine. Dr. Weir suggested that a calculus was lodged somewhere in the course of the ureter, and gave rise to partial obstruction.

THE TREATMENT OF COLD ABSCESS.

Dr. Lange remarked that every one of quite a number of cases of cold abscess which he had seen had terminated fatally after operation, notwithstanding the adoption of full antiseptic measures. In these there existed either extensive caries, which could not be reached by the antiseptic fluid, or there was some obstacle that prevented it from reaching localities far removed from the external opening. In all the cases the patients died from exhaustion due to excessive suppuration. In the treatment of cold abscess he thought the surgeon should take into consideration the stage of the carious process, and whether or not it is possible to remove all the diseased portion of bone, as, perhaps, might be done upon the extremities. Many abscesses depending on disease of the vertebræ should not be interfered with by operation, because we have means at our disposal to cause their absorption more frequently than formerly. The application of ice and the use of other local antiphlogistics and general treatment were safer than opening the abscesses, and in many cases the disease is removed and the patient recovers without being subjected to the danger that quite commonly follows the use of the knife, in spite of the antiseptic precaution. The process is usually a tuberculous one, and, besides, there exists the danger of an irruption of general tuberculosis from absorption. He then referred to five cases of excision of the hip-joint, all the operations being performed at the University of Kiel in the same year, and all the patients dying, in from seven weeks to three or four months, of general tuberculosis, which developed after the operation, and, he thought, depending upon it, because it was not possible to remove all the diseased portion of bone.

On the other hand, he had seen quite a large number of cases of cold abscess which were relieved entirely by the continuous application of ice and the use of general treatment. His plan of management was the following, having special reference to the treatment of abscess in connection with Pott's disease: First and foremost was the constitutional treatment, which should consist of fresh air day and night, food taken at regular intervals, and no dainties; small doses of iron, with carbonate and phosphate of lime; cod-liver oil, pure or in combination with phosphates; and careful nursing. For local treatment, the plaster-of-Paris jacket, removable for summer wear, and the local application of ice, ice-bags on both sides of the vertebral column, continued steadily, perhaps for two weeks, four weeks, or even six months. In some cases in which the symptoms were acute, the child was laid upon the face, and kept in that position for a few weeks with ice applied, when the plaster-jacket could be applied, and the patient allowed to go around. Of course there is no danger in opening a cold abscess after the disease upon which it depends has ceased; but to open an abscess over an active tuberculous osteitic process affecting the vertebral column is not attended by much less danger than before the introduction of the modern antiseptic precautions. In a large number of cases, to prevent decomposition is exceedingly difficult, and the plan of treatment by opening the abscess under the antiseptic spray he thought was not sufficiently safe to make it justifiable, at least, in every case.

The President asked Dr. Lange how he would discriminate between cases in which the process of disorganization in the vertebral column is going on and those in which the process has ceased, in order to determine which cases are suitable and which are not suitable for the operation.

Dr. Lange replied that, in most cases, the indication would be given by the general condition of the patient. For example, if the fever had subsided and

there were no local signs of inflammation the question of operation might be considered. A patient who has been sick for a year or more with caries of the spine is usually debilitated by loss of tissue, spinous processes being prominent, but there may be no fever or pain, and perhaps the general condition is not precisely. In such a case he would be inclined to assume that the osseous process had ceased, that the abscess is merely the remaining accumulation of discharge, and that to open it would not be dangerous, as probably the opening would soon heal.

Dr. Weir referred to two cases which had been under his observation. All the cases did well, and, in that respect, were an improvement upon results obtained by the old method of treatment. Four cases were treated by opening the abscess under the antiseptic spray, and then using the antiseptic dressings, and one was treated by Mr. Callender's method, or hyperidrotion. In all the cases there was a free discharge lasting for some time. In none was he able to determine whether or not the disease upon which abscess depended was progressing.

Dr. L. A. Stimson referred to two cases of cold abscess which occurred in subcutaneous cellular tissue, independent of bone disease. The abscesses had ceased to be tender; evidence of active process had disappeared. Both were opened under antiseptic spray, both were dressed antiseptically, and both continued to discharge until he became tired of renewing the dressings, and he therefore discontinued their use and allowed the discharge to cease as rapidly as possible.

It seemed to him that, if what Mr. Lister claims is true in its fullest extent, when he says that he will open cold abscesses and have the formation of pus cease from that moment, it should be equally true for the aspirator, for the aspirator is free from possible unfavorable influences to which antiseptic surgery is liable.

The President thought it important to recognize the truth of the statement made by Dr. Lange, to the effect that it is not every cold abscess which requires to be opened in order to effect a cure. A remarkable illustration of that fact was offered in the person of Dr. Hubbell, who distinguished himself by making provisions in his will that his body should be dissected. Several years before his death he came to Dr. Sands complaining of a swelling in the left loin, and there was no difficulty in detecting a large fluctuating tumor over the region of the kidney, and extending down to the crest of the ilium. Dr. S. was uncertain whether the fluctuating swelling had any connection with the urinary passages. Tapping was mentioned, but Dr. H., being somewhat advanced in years, and knowing the possible mischief that might accrue, avoided the operation, and passed from under observation for nearly a year, and at the end of that period he reported himself, saying that he was well. While under observation the abscess extended, and evidence was obtained of matter burrowing down upon the buttock, three or four inches below the crest of the ilium; and it also extended upward to the free border of the ribs, but at the time he reported himself it had entirely disappeared. He subsequently died of Bright's disease. Dr. Sands examined the body very carefully, dissected the left lumbar region, but found no abscess. A great deal of connective tissue was found, in which it was difficult to recognize the remains of the kidney. The ureter was imbedded in this mass, which infiltrated the loin, and it was impervious down to its junction with the bladder.

The President also referred to a case of double psoas abscess, seen in Bellevue Hospital, in which absorption did not occur. A young man, act. 17 years, had caries of the lumbar vertebræ, beginning when ten or twelve years old, and there was well marked projection of the spinous processes with swelling in the left groin. Soon after a similar swelling made its appearance in the right groin. In both groins the swelling occupied the position usually occupied by the iliac abscess. The left abscess broke, and about ten days after the right one ruptured and the discharge ceased from the abscesses very slowly indeed. The sinuses remained open for a couple of months. The result was complete recovery.

Dr. Lange was inclined to believe that, in many cases in which favorable reports had been given regarding operative treatment, the disease upon which the cold abscess depended had ceased, and it was possible that the abscess, if let alone, would have healed, perhaps not so quickly, or would have healed under any method of treatment.

The President referred to a case which came under his observation while house surgeon in Bellevue Hospital. The patient had, in early life, suffered from lumbar abscess. He died from other causes, and at the autopsy a caseous deposit was found occupying the precise situation of the psoas muscle. The muscle had entirely disappeared, and the sheath was filled with cheesy matter, the residuum of the old lumbar abscess.

Necrosis of the Humerus.

Dr. Lange presented several pieces of bone obtained from a case of necrosis of the humerus extending into the elbow joint. The patient was nineteen years old; necrotomy was performed about one year ago; the disease was arrested, and only a slight amount of stiffness of the joint remained. The joint was opened during the operation. He raised the question, How shall a joint, which in consequence of osteo-myelitis has become stiff, be treated? Shall excision precede necrotomy, or shall it be a subsequent operation? In the case reported, the patient declined excision, yet he had the use of the arm restored. Dr. Lange referred to one case in which excision of the elbow and the shoulder-joints was performed at the same time with the necrotomy of the entire humerus, by Prof. Esmarch, and the operation was followed by a very good result. He had also heard of a similar case in which the result was very good. He thought excision of the elbow-joint is not so dangerous as that of some other joints, because the tissues are not so apt to undergo infiltration, and the reaction is usually a slight one.

Dr. Stimson referred to a case reported by Langenbeck, of gunshot injury of the shoulder joint, for which four inches of the upper part of the humerus was removed; necrosis of the remaining portion of bone followed, and a few months later a second operation was performed, and the remaining portion of the humerus, with the lower articular surface, was removed. The operations were followed by reproduction of the bone with two articular surfaces.

The Society then proceeded to the transaction of miscellaneous business.

Progress of Cremation.—During the year 1879 fifteen cremations were performed at Gotha, in Germany. The furnace was erected in December, 1878. The average length of time taken for incineration was two hours. The Cremation Society of Milan has burned forty-eight bodies in the last three years.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 23, 1880.

DR. A. E. M. PURDY, PRESIDENT, IN THE CHAIR.

THE Society was called to order at 8 P.M., and the minutes of the last stated meeting read by the Secretary, Dr. F. A. Castle.

OPHTHALMIC NOTES.

DR. C. R. AGNEW read a practical paper having the above title, and directed attention, first, to *the use of electricity in the treatment of cataract.* The conclusion, based upon established and long-recognized principles relative to the nature of the affection was, that it was not impossible that electricity might serve as a tonic, and so relieve some of the symptoms that the credulous might be allured into the belief that they had been cured; but we should be very careful about accepting even such a result. Any form of medical or hygienic treatment which was adapted to special conditions might afford a certain degree of relief. To tell a patient, however, that he had cataract, and then apply electricity, and, upon the removal of one or more symptoms, tell him that he was cured, was, to say the least, unwise, and equivalent to admitting that ours never was a science, but a learned art, and at most an uncertain one; and that the patient's chances of relief were as good under the influence of proprietary medicines as under the management of a medical man who had wisdom and skill. True cataract had not been cured by electricity as yet. Spontaneous dislocation or liquefactive degeneration might occur while remedial measures were being used, and electricity might be among them; but, otherwise, cataract would require for its cure a surgical operation.

SCANT FEEDING IN OPHTHALMIC CASES.

Under this heading Dr. Agnew spoke of forced alimentation, to which public attention had lately been directed by Dr. A. Hutchins, of Brooklyn, in a paper read before the Medical Society of the State of New York. He had followed the plan for many years of giving his patients, notably women, who physically were in an impoverished condition and suffering from asthenopic affections usually, specific directions regarding the articles of food, and the quantity to be taken three, four, or more times daily, as each case might seem to require. Aural diseases of a catarrhal character, with or without middle ear complications, were greatly benefited by systematic and forced feeding, if need be. Too many practitioners contented themselves with giving the diffuse directions, "You must eat more," "You must take better food," without laying down, in black and white, what should be taken, and how often. The following he had for many years both taught and practised:

1. Ascertain the amount of real labor which the duties of the patient impose.

2. Estimate the probable force which the patient possesses; and

3. Estimate with reference to the quality and quantity of food used.

Having done these things, the method pursued was to prescribe in writing, with great emphasis and precision, the daily course of regimen, and provide for every meal, ordering a definite quantity of food to be taken at least three times a day, sometimes every two hours, and, if necessary, the patient might be permitted to consume one or two hours in getting the food down; but take it they must, or else seek other medical advice. In some cases a daily bath, and early going to bed, were of great importance as adjuvants. The foundation of *asthenopia* was very often laid at an early period of life, for both male and female. There should exist a proper relation between the physical form of a man and the labor which he had to perform, and that person was a more or less morbid specimen, the spurious fruit of so-called education, who was deformed or dwarfed in any of the organs essential to the proper performance of the normal functions of the human body.

It was known that *near-sightedness* was rapidly increasing, and it was largely due to a misconception of the principles which should underlie the management of the bodies of the children and youth of our country. Much of the present cramming in schools was productive of evil, and unwise. A graphic picture was then presented, which consisted merely in citing an illustrative case, in which an attempt was being made in a popular school to educate a young girl by giving her regular lessons in fifteen branches.

The great problem should be to teach a few fundamental subjects suited to the stages of the scholar's life, so that each succeeding stratum, so to speak, should be solid instead of porous, and that should be done with more reference to the physical and mental idiosyncrasies of children, and not in so cast-iron and inflexible manner as at the present time. The physical capacity of the scholar should be examined and verified, and the degree of work be made proportionate.

ABUSE OF STRONG AGENTS IN THE TREATMENT OF SIMPLE CATARRHAL AFFECTIONS OF THE EYE.

It would be much better, said the speaker, if the general practitioner should never apply either the solid stick or strong solutions of nitrate of silver or sulphate of copper, etc., to the eye.

For diffuse and chronic catarrhal inflammation of the conjunctiva, he recommended the following, to be used in the form of spray:

℞. Tannic acid	grs. v.
Glycerine	ʒ ij.
Biborate of soda	ɔ ij.
Camphor water	ʒ iv.

M. and filter.

In all chronic affections of the eye the Turkish bath was of great service, as, for example, in extended inflammation of the cornea, iritis, etc. Pilocarpin, used hypodermically in sufficient doses to produce profuse salivation and sweating, was also specially serviceable in many of the chronic cases.

THE OPHTHALMOSCOPE IN CEREBRAL DISEASE.

Dr. Agnew expressed a lack of confidence in the value of the ophthalmoscope in recognizing the presence or absence of cerebral congestion. In the first place a reliable ophthalmoscopic examination was most difficult to make. In the greater number of "jaded heads" the ophthalmoscope, so far, had given only negative results. That we might, by looking into the eye with an ophthalmoscope, tell whether the brain was congested or not, he did not believe, as a rule, was true. Evidence of congestion was rarely present in cases of "jaded heads."

The paper being before the Society,

DR. H. D. NOYES referred to a remark made by a gentleman in days when little or nothing was known about refraction of the eye, as taught in modern times, namely: "When people come to me complaining

of symptoms asthenopic in character, I commonly go through with such a formula as this. I ask something about the habits of life—with respect to work and food, ordinary surroundings, medical history, etc., and make such examination as is necessary to eliminate actual diseases of the eye, and then tell them, 'You are suffering from what is known as asthenopia. What I wish you to do is to take the best dinner you can get, drink half a bottle of wine, and do the same thing every day for a few days, and if at the end of that time you find your eyes are better, I think you can get well; but if you are not able to use the eyes better after using good food and some stimulants, I cannot help you.'"

Dr Noyes thought that in the formula recited laid the pith of Dr. Agnew's remarks upon that class of cases, and on the subject of forced alimentation he had suitably laid great stress. With reference to *cataract* his experience corroborated that of the author of the paper. Cases were not at all uncommon in which there was no noticeable progress in the cataract for many years, and in such cases it was very easy for the person to become deceived by the statement that he had been cured. With regard to *school life*, it was to be noted that knowledge was one thing and wisdom was another. In the modern schools an effort was made to force the knowledge into the pupils, perhaps to the detriment of wisdom, certainly to the detriment of their physique. Much that had been said by the reader appealed to the experience of general practitioners, and Dr. Noyes commended all the suggestions as exceedingly timely and exceedingly wise.

Dr. Charles S. Bull endorsed the statements in the paper most heartily, but especially the remarks made relative to the limited power of the ophthalmoscope. He believed that it had only a very limited power as a cerebroscope. The diagnosis of the inflammatory conditions of the optic nerve, and, inferentially, corresponding conditions of the brain, had been, for the most part, made by persons who were not sufficiently acquainted with the instrument to diagnosticate any of the more delicate affections of the eye. He thought it important that the general practitioner should know how limited the ophthalmoscope was as a cerebroscope.

Dr. O. D. Pomeroy thought it would not be personal, perhaps, to say that he was not acquainted with a single neurologist in the city of New York whom he knew thoroughly understood diagnosticating refractions by means of the ophthalmoscope. The only method by which the eye could be examined exhaustively was the upright, and that could not be practised skilfully without understanding how to diagnosticate refractions. No man could make a thorough ophthalmoscopic examination without such ability, and he knew of no one who possessed the requirement except ophthalmic surgeons. Ordinarily, neurologists were unable to state whether or not there was any disease in the eye.

With regard to nutrition, he made it a rule in many cases not to undertake the treatment of otitis, unless the patient would agree to cease work and feed well.

With regard to cataract, he thought it true that perfect crystalline lenses were about as rare as perfectly moral men.

With reference to the use of the sulphate of copper, he differed somewhat from Dr. Agnew, and used it a great deal. Of course, if used at all excessively, it would cause undesirable irritation. He thought he could touch the inflamed conjunctiva so lightly with a crystal of sulphate of copper as to produce nothing more than slight lachrymation, and a trifle of sneezing, which would be produced by the milder applications.

Dr. I. A. Corlis referred to the mismanagement of the pupils in boarding-schools. The same was true of young children. Some parents seemed to dread that their children would be overfed, and so produce an unseemly exterior, and by the time they had reached the age of twelve or fourteen it was found very difficult to make them take a sufficient quantity of food to meet the physiological requirements for growth and repair.

Dr. Mitchell referred to the beneficial influence exerted by a Turkish bath upon a case of iritis. Prior to the bath it resisted treatment, but as soon as the bath was taken the patient improved rapidly; and then, after a mercurial bath, the synechia readily improved, and the patient made an excellent recovery.

Dr. Agnew remarked that he did not wish to interdict the use of nitrate of silver and the sulphate of copper in certain ways, in chronic diseases of the conjunctiva, and only referred to the facility with which they were used in slight catarrhal affections which were limited, and which would get well of themselves, and not infrequently, so used, produced cicatrices that were a permanent source of irritation.

THE AUDIPHONE.

Dr. Agnew further remarked that he had yet to see a person who had been benefited by the audiphone to the extent that had been claimed for it. He exhibited an extemporaneous audiphone made by one of his patients, who declared that it was more serviceable to her than any of those found for sale. It consisted of an ordinary Japanese fan, with a hollow reed handle, and delicate, radiating fibres covered with vegetable tissue, and over that surface had been placed a coating of shoe-blacking and a coat of shellac. The edge was bound by a little strip of brass, and at the central part a strip of silver was used for binding, so that when placed in the mouth the disagreeable taste of the brass would be avoided. The fan was bent so that a broad convex surface caught the impression which was transmitted through the teeth, as it was held with the concave surface toward the body and the edge against the teeth.

Under the head of miscellaneous business the names of all members delinquent in the payment of dues for more than one year were read, and it was voted to publish the list in the minutes.

WHO FOUNDED THE NATIONAL MEDICAL LIBRARY?

The Secretary read the following:—

WASHINGTON, February 3, 1880.

To the Secretary of the Medical Society of the County of New York:

DEAR DOCTOR—As my attention has several times been called to the communication by Dr. Wm. A. Hammond relative to the library of this office, read at the annual meeting of the Society, October 27, 1879, and more especially to the report of this communication given on page 472 of the New York MEDICAL RECORD for November 15, 1879, with requests for explanations, I deem it proper to make a statement on the matter to the Society.

From the report in the RECORD, some have inferred that I claim to have been the founder of the National Medical Library, although the letter of Dr. Hammond, as printed on page 40 of the minutes of that

meeting, makes it very plain that I have made no such claim.

The facts of the case are simply as follows:

For many years there was a small collection of medical books and journals in the Surgeon-General's office at Washington, which collection was commenced by Surgeon-General Lovell prior to 1836.

At the commencement of the war this collection amounted to between three and four hundred volumes.

Dr. Hammond entered on his duties as Surgeon-General April 28, 1862, and left Washington August 30, 1863, after which date he was not on duty in this office. During this interval three hundred and fifty-nine volumes were purchased for the use of the office, the principal works being a set of the "Annales d'Hygiène" and a set of the "Boston Medical and Surgical Journal." During the years 1864 and 1865 about 1,000 volumes were added to the library, mainly works selected by Drs. Woodward and Otis.

When the library came under my charge, in the fall of 1865, it contained, as shown by a catalogue made at the time, about 1,800 volumes. At this date it contains about 50,000 volumes and 60,000 pamphlets.

Very respectfully and truly yours,

JOHN S. BILLINGS,
Surgeon U. S. Army.

DR. P. BRYNBERG PORTER introduced a resolution asking Congress not to repeal the present law making quinine free of duty. On motion it was referred to the Comitia Minora.

The Secretary tendered his resignation, which the Society, by vote, refused to accept. The Society then adjourned.

WEST CHICAGO MEDICAL SOCIETY.

February 9, 1880.

THE PRESIDENT, DR. BRIDGE, IN THE CHAIR.

TRAUMATIC TETANUS, WITH RECOVERY.

DR. E. W. LEE reported a case of *traumatic tetanus*, with recovery.

Seven weeks before the case came under his observation the man had received a crushing injury of the outer side of the lower third of the leg. It had been dressed by a physician, but a fracture of the fibula was not discovered. On visiting the man the first time Dr. L. noticed the *risus sardonicus*, that grin which marks a case of tetanus. The patient complained of a tightness about the chest, as though a belt was drawn tightly around the body. What was curious was the fact that the patient declared that these symptoms had existed from a few days after the injury. This gave the case the appearance of chronic tetanus. The injured part presented an unhealthy but small ulcer, from the bottom of which a sinus led to denuded bone.

Bromide of potassium and hydrate of chloral were given—the latter in 20 to 30 grain doses—with instructions to repeat often enough to keep the man in a stupor.

The next day he was worse, and a thorough examination of the wound was made—the patient being anæsthetized. A portion of the fibula, over an inch in extent, was found necrosed; this was removed. He grew worse, and in one week all the symptoms of acute tetanus were developed. He had convulsions, and the abdominal muscles were in a state of tonic contraction. The bromide and chloral had been continued. Now calabar bean extract was given, one-eighth to one-quarter grain every two hours. It produced no effect. Squibb's extract was then procured, and one-eighth grain was given at a dose hypodermically. At first four doses each hour was given; soon the convulsions abated. The doses were given less often, and in twelve hours an injection every two hours was sufficient to control the convulsions. The effect was repeatedly observed that, following a dose of the medicine, the convulsions grew less, while invariably a prolonged omission of it was followed by an increase of the spasms. By the seventh day one or two injections daily were all that was required. A good recovery was made; seven weeks had elapsed since a convulsion had occurred.

DR. S. J. HOLMES related a case of traumatic tetanus that recovered under the influence of calabar bean, while he was an interne in Charity Hospital, New York. The spasms had appeared the eleventh day after the injury (the fracture of a finger). One-half to one grain of Squibb's extract of calabar bean was given every three hours throughout the course of the disease.

TREPHINING IN DEPRESSION OF SKULL AND COMA, WITH IMMEDIATE ALLEVIATION OF THIS SYMPTOM.

DR. LEE related a case of fracture of the skull—a child who had fallen ten or twelve feet and struck upon its head. The skull was fractured transversely across the crown, and the depression was very marked. It was stated that the child had walked several yards after the fall, but when he was called the patient was in a condition of perfect unconsciousness. He trephined and lifted the depressed bone with a pair of forceps, when consciousness instantly returned. The child did well for several days, when fever set in and it died.

POISONING BY CHLORATE OF POTASSIUM.

DR. ADELIA BARLOW related three cases of what she believed to be the poisonous effects of chlorate of potassium given in what had been supposed to be poisonous doses. The first case was in a child nineteen months old, who had scarlet fever. The case had been treated with iron, quinine, and chlorate of potassium. The child was convalescing, the quinine and iron mixture had been mostly discontinued, that of the chlorate was continued, the patient swallowing a drachm of the salt every twenty-four hours. Suddenly, one evening, the patient passed into collapse, the trunk of the body became feverish, but the extremities were cold and the breathing stertorous. There was every evidence of poisoning. The child slowly revived under the influence of large doses of quinine and brandy. She could attribute the symptoms to nothing but the chlorate.

The second case was in a child eight months old. Thirty grains daily of the chlorate was given. After a few doses had been given, symptoms similar to those of the first case came on.

The third case was in an infant, three weeks old, with thrush. It took only one dose of the medicine. The mother saw that poisonous symptoms had been produced, and refrained from giving more. The symptoms were like those of the first case.

She was sure that in neither case was there any suppression of urine.

DR. HARCOURT and DR. LYMAN discussed this subject, and both expressed the view that the drug in question should be given with more caution than had generally been thought to be necessary.

Correspondence.

THE SOCIAL POSITION OF THE DOCTOR.

To the Editor of The Medical Record.

Dear Sir:—In your issue of February 11th occurs the following sentence: "The social position of the doctor in this country is not, on the whole, a very high one; because the individual doctor has not the means, and often, it must be confessed, not the education or taste, to make it such." These remarks, it seems, were elicited by some strictures made by Dr. J. Milner Fothergill, of London, in a letter in a recent number of the *Philadelphia Medical Times*, respecting the social position of medical men and their wives in Great Britain, the latter of whom he declares to be mere pariahs or social outcasts without any position whatever. With this statement of Dr. Fothergill I have no concern, although I take leave to express my conviction that it is entirely erroneous.

To the assertion of the Record I am obliged to take exception, for I am sure it is not true. I have lived a good while in the world, and having seen a great deal of society, I am safe in asserting that there is no profession, vocation, or pursuit which, on this side of the Atlantic, enjoys a higher social status than the medical, the clerical not excepted. The refined and educated American physician is a prince among men, and his wife is ever his equal in the social circle. Indeed, she is often a leader in, and a queen of, society. Who has not heard of the late Mrs. Octavia Walton Le Vert, the wife of the distinguished Dr. Henry S. Le Vert, of Mobile, Alabama? This lady, so accomplished as a linguist, a writer, and a conversationalist, was everywhere honored and caressed by the good and the great at home and abroad. No American woman ever received more homage or consideration at foreign courts than she did. For many years she was a leader of fashion in her own city, rendering her house one of the most attractive in the country, and adding greatly to the reputation of her celebrated husband. Mrs. Le Vert's case is not a singular one. Many similar instances might be cited of the wives of medical men, who, by their charming manners, high mental culture, great intelligence, and high refinement, have attained to the highest social rank. In my own city the educated physician is, and always has been, the peer of the best man in the community, whatever may be his calling. There is never any large dinner-party, an evening gathering, or a club-meeting, at which there is not always a full representation of medical men, who never fail to hold their own by their good breeding, their general intelligence, or the elegance of their manners. The Wistar parties, so called in honor of Dr. Caspar Wistar, the celebrated Professor of Anatomy in the University of Pennsylvania, which, for nearly half a century, were the acknowledged centres of the refinement and intellectual culture of Philadelphia, were largely composed of medical men, among others, of Chapman, James, Dewees, Hays, Bache, René La Roche, Robley Dunglison, and George B. Wood, men who, in a social point of view, were the peers of the Binneys, the Sergeants, the Ingersolls, the Whartons, the Cadwaladers, and other distinguished citizens. The wives of these men were all on an equal footing. Where their husbands went they went; they were not pariahs or social outcasts. On the contrary, they were refined and cultured women, the peers of any similar number of women in the country. The Morgans, Shippens, Rushes, Wistars, Bartons, and Dorseys of former days, occupied along with their wives an equally commanding social status, and what is true of those people is equally true of the present generation of medical men, and of their wives, in this city.

During my residence at Cincinnati and at Louisville, I never failed in attending an evening party, a dinner, or a social entertainment of any kind to meet with some of my professional friends and their wives, sons, or daughters; and I speak advisedly when I declare, although it may be at the expense of repeating myself, that there is not a city or town of any considerable size in the Union, in which the same state of things does not obtain. If you look at the medical profession in your own city, you will find a further illustration of the truth of my statements. In 1828, I was at a Thursday evening reception given by the late Professor David Hosack, one of the great medical luminaries of his day, to the New York Philosophical Society, which was graced by a large number of distinguished jurists, divines, artists, and literary gentlemen, including, as I well remember, such men as Francis, Macneven, Mott, Kearney, Rodgers, and the great and good but eccentric Samuel Latham Mitchill, and their wives. It was one of the most brilliant assemblies of the kind I have ever witnessed. It is not necessary to ask what was the social status of such men as Bailey, Bard, Jones, Miller, Wright Post, and others, physicians whose names and fame are indissolubly associated with the glory of New York. It is folly to suppose that these men were deprived of the entrée of the best society of your great city.

The refined and cultivated society of Boston has always had a large share of the medical element. Its doors have always been widely open to the Warrens, the Haywards, the Channings, the Bigelows, the Jacksons, the Shattucks, the Bowditches, the Storers, the Reynoldses, and others, as they still are to their descendants. In no section of the United States did society for a full century enjoy so high a status as that of Charleston, South Carolina. It was, beyond question, at one time, the most brilliant and aristocratic society in this country. Nowhere has there been at any time on this continent a higher type of civilization, or a greater amount of elegant and refined breeding, than in this once great and famous city; famous for its pretty and accomplished women, and its noble, chivalric, and intelligent men. Its social entertainments were always of the most recherché and costly character. More old madeira and sherry, burgundy, and champagne were consumed, and a greater number of terrapins annually slaughtered at these réunions than in any other city of its size in America; and who that is familiar with the inner life of Charleston, as it existed only a short time ago, does not know that its society was largely indebted for the éclat which it so long enjoyed, to its medical men and their wives? The elegant and refined S. Henry Dickson was a host in himself—a perfect type of the true gentleman who would, in any land, have graced the society of princes. Who is not familiar with the high social position of the Ramsays, the Porchers, the Ravenels, the Holbrooks, the Geddingses, the Prioleaus, Frosts, and other distinguished men whose names adorn the medical history of the United States?

What is true of our larger cities in this respect is true, emphatically true, of every town, village, and hamlet of the Union. Go where we may, the refined and cultured physician is a man of mark, not a whit

inferior in his social position to the clergyman, the lawyer, the scientist, or the merchant prince. A great deal is said at the present day of the want of refinement and of the defective education of the medical student, as if he were the veriest boor in Christendom, hardly half civilized, unwashed, unkempt, and dressed in the shabbiest possible garb. We are all agreed that our systems of instruction are sadly out of joint; that they are not what they should be, or what, by and by, they must and will be; but I am quite sure that if you were to drop in some day into my lecture-room, while I am engaged in addressing nearly 600 students, assembled from all parts of the country, including representatives from different foreign lands, you would be surprised at their orderly conduct, their gentlemanly appearance, and their intelligent countenances. Many of these youths are not only well educated, but they have been reared under the best influences, and are destined to make their mark in the profession as well as in the social circle. Our army and naval surgeons are, as everybody knows, everywhere admitted into the very best society, both at home and abroad. Again, not a few of our young physicians marry into our most distinguished families, which would assuredly not be the case if they were not well-bred, cultured, and meritorious men.

It might seem invidious in me, if not in bad taste, to institute a comparison between my own and the other learned professions; but I think you will bear me out in the assertion that if we take one hundred medical men, as we meet with them in our towns and cities, and place them side by side with an equal number of clergymen and lawyers, they will lose nothing by the comparison either in mental culture, high refinement, or social position.

I am not sufficiently familiar with the social status of medical men in Great Britain, but, unless I greatly err, Dr. Fothergill has been inadvertently betrayed into an unfortunate slander upon his professional brethren, which no one will probably regret more than himself, or be more anxious to correct. My two visits abroad brought me into contact with a large number of medical men in England, Ireland, and Scotland, and I can conscientiously declare that I did not meet with a solitary one who was not entitled to be called a "gentleman." There are, of course, different grades of society, and it cannot be expected that every medical man should, even if he aimed at such an absurd performance, be received into the highest circles. There are comparatively few in any profession who are thus honored.

Every man holds his social position in his own hand; if it be not his birthright, he can, if he choose, or is worth anything at all, gradually attain it, despite the misfortunes of circumstances. The requirement for admission into society in Philadelphia is said to be family, or blue blood; in New York wealth or money; and in Boston literature or mental culture. This may be so, but it is so only in a certain degree, and these landmarks are rapidly becoming merged into one another. Character alone should be the test of social distinction in a truly civilized country.

I cannot agree with you when you say that social position is not a thing for which men should struggle. I cannot see how this can interfere with a physician's usefulness. On the contrary, I regard it as one of the highest and most sacred duties of the medical man to cultivate the graces and amenities of social life. It is the absence of this quality that lowers the profession so much in public estimation, and reduces it to the level of the more ordinary pursuits of life, as illustrated in the conduct of the mechanic, the tradesman, and even the common laborer. No, no; let the medical man aspire to be a refined and cultured gentleman, and do all he can to adorn the higher walks of life, for just in proportion as he does this will he be respected by the community, and add to the respect and dignity of his profession.

Very respectfully your obedient servant,

S. D. Gross.

Philadelphia, February 25, 1880.

[We are glad to hear from Prof. Gross on this topic. Except in a few unimportant particulars, to which it is unnecessary now to refer, we entirely agree with him in the position he has taken. But we consider it quite fortunate for the readers of the Record that the points of difference were considered by him of sufficient importance to provoke the writing of his very interesting epistle.—Ed.]

TWO CASES OF INERTIA UTERI.

To the Editor of The Medical Record.

Sir:—It has occurred to me that the history of two cases of inertia uteri, which have come to my knowledge, might be of interest to the readers of the Record. Mrs. D., a native of Ireland, 47 years of age, the mother of ten children, was taken with labor-pains the 11th of last November. Her physician was sent for, although no trouble was anticipated, and she had been confined usually by a nurse, and no physician had been called. Her physician remained with her through the 12th and waited for nature to accomplish her purpose. The pains were short and grew less and less, and finally ceased. Some time during the night of the 12th Dr. F. was sent for, and at his suggestion the forceps were applied at the brim of the pelvis. No effect upon the progress of the delivery was possible with the forceps, and at 8 A.M. of the 13th I was summoned to the case. Thinking that the forceps might yet be efficacious, I reapplied them, but with no better success than before. The woman was very patient, and all this time had no pains of any appreciable amount. Upon consultation, craniotomy seemed best, and the brain was broken up and the head extracted. The shoulders next engaging in the passages, were delivered by getting one arm down and then the other, and the body finally drawn away by force, coming as a cork from a bottle, so completely was the passage filled. The mother was a large-framed, muscular woman, with broad pelvis, but the difficulty was threefold: the entire inertia of the uterus, the extraordinary development of the child, which must have weighed sixteen to eighteen pounds, and the peculiar hardness of the child's flesh, which Dr. F. described as resembling cold tallow. The child had evidently been dead some hours, and perhaps days. The mother made a good, though slow recovery, but was much troubled with incontinence of urine for some weeks. We had noticed a remarkable dilatation of the urethra after the delivery, and I feared that the incontinence might be permanent. However, a few weeks later she told me she was "all right."

The other case was reported at the annual meeting of the Union Medical Association of Washington, Warren and Saratoga Counties, by Dr. Gibbs, of Fort Ann, who saw the case in consultation with Dr. Sarah J. Finch. The patient was a young woman, 24 years of age, one and a half years married, who had experienced one miscarriage. She had had some cardiac difficulty for several years, and after her miscarriage had been treated for it. During the time of

her confinement her pulse was very irregular and fluttering. She was taken at first with slight pains, and these increased somewhat, and, with some intermission, continued for twenty four hours. After that time there were no very effective pains, full doses of ergot merely increasing them for a brief period. Dr Gibbs was called in, the forceps applied at the upper strait, and no amount of force which the doctor thought proper to use was of any effect. Craniotomy was thought expedient. Another physician, of more experience, was sent for, and asked to perform the operation, which he declined to do, saying it was unnecessary. After waiting nearly twenty four hours more, with no return of the pains, Dr Gibbs performed craniotomy and removed the child, much decomposed, and weighing eleven or twelve pounds. There was no contraction of the uterus after delivery, and the placenta was removed by introducing the hand and peeling it from the walls of the uterus, which even then did not contract. Cold applications externally caused some slight contractions, but there was no flooding, no fresh blood appeared, even when the placenta was thus forcibly removed, and no natural lochia. The patient made fair progress toward recovery, began to sit up a part of the day, when, about three weeks after the delivery she seemed to have taken cold, had a severe chill, was troubled about breathing, and within twenty-four hours was dead. No satisfactory explanation of the causes of this condition was suggested at the meeting. Will some of the readers of the RECORD, who have had similar cases, give their ideas on the subject?

JAMES S. COOLEY, M.D.

SANDY HILL, N. Y., Feb. 18, 1880.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from February 22 to February 28, 1880.

BYRNE, C. C., Major and Surgeon. Granted leave of absence for twenty days. S. O. 2, Dept. of Dakota, February 18, 1880.

LORING, L. Y., Capt. and Asst. Surgeon. When relieved by Asst. Surgeon D. M. Appel, to proceed to Ft. Dodge, Kan., and report for duty at that post. S. O. 39, Dept. of the Missouri, February 20, 1880.

APPEL, D. M., First Lieutenant and Asst. Surgeon. Assigned to duty at Ft. Supply, Ind. T., relieving Asst. Surgeon Loring. S. O. 39, C. S., Dept. of the Mo.

COOPER, GEO. E., Lieut.-Colonel and Assistant Medical Purveyor. To be relieved, temporarily, in the charge of the Medical Purveying Depot in San Francisco, Cal., by Capt. H. Johnson, Medical Storekeeper. S. O. 48, A. G. O., March 3, 1880.

HEGER, A., Major and Surgeon. Having reported in compliance with orders from the A. G. O., is assigned to temporary duty at Department Headquarters. S. O. 42, Department of Texas, February 26, 1880.

MUNN, C. E., Captain and Asst. Surgeon. Granted leave of absence for one month. S. O. 44, Department of the Missouri, February 27, 1880.

BROWN, P. R., Captain and Assistant Surgeon. To report in person to the President of the Medical Examining Board for examination for promotion, and on completion of the examination, to the Commanding General, Department of the East, for assignment to duty. S. O. 47, A. G. O., March 2, 1880.

FISLEY, J. A., Captain and Assistant Surgeon. To report in person to the President of the Medical Examining Board, in session in New York City, for examination for promotion, and, upon completion of the examination, to the Commanding General, Department of the East, for assignment to duty. S. O. 47, C. S., A. G. O.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending March 6, 1880.

Week Ending	Typhus Fever	Typhoid Fever	Scarlet Fever	Cerebro-spinal Meningitis	Measles	Diphtheria	Small-pox	Yellow Fever
Feb. 28, 1880...	0	7	49	4	176	44	0	0
March 6, 1880..	0	6	43	3	144	35	0	0

A CORONER'S BILL to prevent unnecessary inquests is before the Ontario legislature. The *Canada Lancet* states that it provides that a coroner, before summoning his jury, shall make affidavit before a justice of the peace that he believes the deceased died through violence or unfair means, and that an inquest is needed. The bill, if it becomes a law, would lessen the number of post-mortems, but would probably increase the duties of the coroner in other ways.

DEATH OF A MEDICAL STUDENT FROM DIPHTHERIA. —Another Paris medical student has fallen a prey to diphtheria. M. Reverdy was one of M. Bouchut's assistants at the Hôpital des Enfants Malades, and, although he had become seriously ill, continued his work until M. Bouchut at last insisted on his going home. It was, however, too late, and he died within a week. He was the seventh medical student who died from diphtheria contracted in the same hospital during the past year.— *British Medical Journal.*

MEASUREMENT OF LIMBS.—A correspondent of the *Cincinnati Lancet and Clinic* writes that Dr. Thos. G. Morton has been measuring the limbs of the boys of Girard College. Among 300 he found asymmetry the rule, the difference varying from a fraction of an inch to an inch.

REPORT OF SEMI-CENTENNIAL ANNIVERSARY OF THE DISTRICT MEDICAL SOCIETY FOR THE COUNTY OF BURLINGTON, N. J., held April 17, 1879. This report embraces an address of welcome by Dr. R. H. Page, and a historical address by Dr. Jos. Parrish. The latter is a carefully prepared document, and contains many interesting sketches of the early members of the District Medical Society. It appears that the Society has taken a prominent part in medical, sanitary, and educational work, and has earned a right to self-congratulation on its having reached a fiftieth birthday.

THE AMERICAN VETERINARY COLLEGE.—The commencement exercises of the American Veterinary College were held February 27th. Prof. D. B. St.

John Roosa delivered the address to the graduating class. The President of the Board of Trustees, Samuel Marsh, Esq., conferred the degree of Doctor of Veterinary Surgery on eight gentlemen. The valedictory was delivered by E. R. Wing, of the graduating class.

The Founding of the New York Hospital.—In a work just published by the Churchills, in London, on "Pay-Hospitals and Paying-Wards throughout the World," by Henry C. Burnett, occurs the following: "In March, 1878, a new hospital, intended almost exclusively for the well-to-do classes, was established by Dr. W. H. Van Buren in New York. The cost of this hospital and the grounds which surround it is estimated at £180,000," etc., etc. It will probably interest Dr. Van Buren as much to know of his magnificent benefaction, as it will the profession in America to learn that the New York Hospital owes its being to their esteemed fellow-countryman.

Iron and Digitalis.—It is often very desirable to give these remedies together. A common way has been to administer the ammonio-citrate of iron and tincture of digitalis. According to Mr. F. Y. Livy, however, in the *British Medical Journal*, a mixture of tincture of muriate of iron, tincture of digitalis, and dilute phosphoric acid, is the best formula. The acid prevents the formation of a tannate, and is useful in case there is any stomachic disorder.

We have tried the above mixture, and find it without precipitate, as described.

The Northampton State Lunatic Hospital and the Curability of Insanity.—The twenty-fourth annual report of the Northampton Insane Asylum, or, as it now calls itself, Lunatic Hospital, has just been received by us. Under the efficient care of Dr. Pliny Earle, the institution seems to be kept in excellent condition. By the work of its patients and by its pay-patients it manages now to be self-supporting.

Dr. Earle has for some time taken the ground that the curability of insanity has been much exaggerated. He discusses this question at length in the present report. In his own asylum, devoted largely to chronic cases, there were admitted during the past year 106 patients. Of these, 23 died, 26 were discharged cured, 28 improved, and 14 unimproved. Several of the 26 cases of cure were liable to a return of the disease; so that the number of actual cures is less than 24 per cent., and much below that usually given by asylums. Dr. Earle is of opinion, however, that a lower percentage would be given elsewhere, if more care were taken in the statistics, and the errors due to reckoning the number of cures on the same person avoided.

We notice that the ratio of cures at the Northern Hospital for the Insane, in Wisconsin, is about 60 per cent.

Dr. Friedrich Wilhelm Theile, at one time Professor of Anatomy in Bern, died recently in Weimar, aged 78 years. When 26 years of age he lectured on anatomy and anthropology in Jena, and was soon afterward promoted to a professorship in that university. In 1834 he was called to the new university of Bern, to fill the position of Professor of Anatomy, a position which he retained for nearly twenty years. He was at one time Rector Magnificus of the University of Bern. In connection with Wagner, Henle, and others, he edited the revised edition of Sömmering's Anatomical Work, for which he contributed the section on Muscles. Since 1853 he had practised medicine in Weimar.

Effects of Smoking on the Heart.—Some years ago M. Decaisne drew attention to the fact that tobacco-smoking often causes an intermittent pulse. Out of eighty-one great smokers examined, twenty-three presented an intermittent pulse, independent of any cardiac lesion. This intermittency disappeared when the habit of smoking was abandoned. He also studied the effects of smoking on children from nine to fifteen years of age, and found that it undoubtedly caused palpitation, intermittent pulse, and chloro-anæmia. The children, furthermore, became dull, lazy, and predisposed to the use of alcoholic drinks. Recently he reported to the *Société d'hygiène* the results of his observations on the effects of smoking on women. Since 1865 he has met with and observed forty-three female smokers. Most of them suffered from disturbances of menstruation and digestion, and eight presented very marked intermittency of the pulse without any lesion of the heart. He gave detailed accounts of these eight cases, in which all treatment directed against the intermittency proved utterly useless, while the suppression of tobacco was invariably followed by improvement and very often by complete disappearance of the phenomenon.—*Gazette Obstétricale.*

Nursery and Child's Hospital.—The annual meeting of the Nursery and Child's Hospital Society was held recently at Fifty-first street and Lexington avenue. The financial report showed a total received for the year ending March 1, 1880, of $147,050.50, of which $12,468.79 remained in hand. The receipts of the Charity Ball were in excess of any previous season for several years.

Fourth Biennial Report of the Iowa Hospital for the Insane, for 1878 and 1879, Dr. A. Reynolds, Superintendent.—This report shows that the present number of inmates is 450, an increase of 132 in the past two years. The per cent. of recoveries on admissions has been 16; that of deaths, 13. There are now in the State about 1,300 insane. Dr. Reynolds makes some very sensible remarks in protest against expensive and luxuriant quarters for the insane. He advocates a State hospital for the chronic insane. A great deal is evidently done at the asylum to entertain the patients.

Diphtheria in Russia continues its ravages, and is carrying off from 50 to 70 per cent. of its present population. There are not enough doctors nor hospitals, and the people have no idea how to take care of themselves. A prevalent custom is, after the death of a child, to place a piece of bread in its mouth, and then, having made the sign of the cross, to take it out and distribute it among other members of the family, by whom it is eaten. Organized efforts are being made to furnish relief.

Extraordinary Case of Twin Pregnancy.—Dr. L. A. Wohlfarth, of Rosedale, Kansas, relates the following interesting case: He found Mrs. S—— in her ninth labor; the waters had come away and the os dilated to the size of a dollar. There being no pains he went away, and was not called again until three days later. He then found an arm-presentation. Version was performed and the child delivered. After waiting an hour for the placenta, examination revealed a second child, with head-presentation. This was soon delivered, and was found to be completely enclosed in a double placenta, and also enveloped in a sac, of the thickness of ordinary sheepskin. This latter condition, together with the position of the first child and the length of the labor, make the case an unusual one.

THE MEDICAL PROFESSION AS A CALLING.—It is strictly true that the medical profession is overcrowded, and cannot be regarded as an eligible 'calling' for needy men, or indeed for men who are not practically independent of their work as a means of livelihood. The laborer is worthy of his hire, and it is in the last degree desirable that a full and fair tariff of fees should be maintained, but we cannot recommend young men without sufficient private resources to enter the profession. It is because a serious mistake has been too often made in this matter there are in our ranks many hundreds of able but distressed practitioners who contend with eagerness among themselves for appointments of almost any class which seem to offer the means of bare sustenance. The profession labors under great disadvantages resulting from its crowded state and the impecuniosity of its members. One, though not the only, reason why the scale of payments for public services—for example, attendance on the sick poor—is so low, will be found in the number of eager applicants for any vacant post, let the emolument be small as it may. Parents, and young men of narrow means, will do wisely to be warned, and look elsewhere for a vocation which brings adequate rewards. There is not a word of exaggeration in the statements which have been recently made on the subject, and we trust they will have a deterrent effect.—*Lancet.*

THE PRICE OF QUININE is now $3.20 per ounce; that of dextro-quinine, $1.50 per ounce; of cinchonidia, $1.10; opium is at $5.50.

THE COLLEGE AND CLINICAL RECORD. This a new monthly journal, to be conducted especially in the interests of the graduates and students of Jefferson Medical College. It is edited by Drs. Richard J. Dunglison and Frank Woodbury, both of whom have had considerable experience in journalism. The first number is well printed and contains a number of valuable articles. It informs us that the number of matriculates for the year 1879–80 is 590.

RESIGNATION OF PROFESSORS.—Dr. F. D. Cunningham, Professor of Anatomy in the Medical College of Virginia, has offered his resignation, to take effect with the completion of the present winter course of lectures. Dr. A. B. Cook, Professor of Surgery in the Louisville Medical College, has resigned his position.

HIGH MORTALITY RATE IN LONDON.—The per cent. of deaths in London has of late been extraordinarily high. In the week ending January 31st, it was 31.6 per thousand; and in the succeeding week, 48.6 per thousand. This is without parallel since the cholera epidemic, and is due to the action of persistent dense fogs upon the respiratory organs of the aged. The excessive mortality is confined chiefly to those above the age of sixty. The mortality rate in London sometimes falls as low as eighteen per thousand.

BURNING OF A MEDICAL COLLEGE.—The building occupied by the Medical College of Indiana, Indianapolis, was destroyed by fire on February 10th. Most of the apparatus belonging to the institution was lost.

KINGS COUNTY MEDICAL SOCIETY.—The library of this society is being greatly enlarged through the efforts recently made by some of the members. A committee was appointed at the February meeting to consider the point in hospital management, regarding paid medical attendance, that has been suggested by Dr. Prout.

MEETINGS OF STATE MEDICAL SOCIETIES. The Missouri State Medical Society holds its next annual meeting at Carthage, on the first Tuesday in May. The Illinois State Medical Society meets at Belleville two weeks earlier.

THE FACULTY OF THE ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS recently gave a dinner to the Board of Trustees. We are informed by the *St. Louis Clinical Record* that one of the results of the meeting was the raising a fund for the erection of a new college building and the conversion of the old one into a hospital.

THE NEW PENNSYLVANIA STATE HOSPITAL FOR THE INSANE, at Norristown, was formally transferred on Feb. 18th from the Building Commission to the Board of Trustees. The buildings are said to be well constructed, and are substantial rather than ornate. Their cost is at the rate of $744 a bed, which is less than the sum appropriated for the purpose.

CALLING FOR A STATE BOARD OF HEALTH.—A petition has been drawn up and presented to the State legislature, recommending the establishment of a State Board of Health for New York. Among the signers are Dr. Willard Parker, Howard Potter, the Rev. Dr. Bellows, A. A. Low, William E. Dodge, Charlton T. Lewis, Frederick Law Olmsted, Dr. Cornelius R. Agnew, Theodore W. Dwight, Peter Cooper, Abram S. Hewitt, Chancellor Crosby, and Jackson S. Schultz. The bill providing for this board is said to have a very good prospect of success.

THE CORONER SYSTEM IN ENGLAND.—A bill is now before parliament to remedy the defects of the present English coroner system, by securing coroners or medical examiners who are properly qualified by scientific study. During the past forty years there have been many failures in the administration of justice through inefficiency of the present system.

Original Communications.

THREE CASES ILLUSTRATING LUXATION OF THE ULNA IN CONNECTION WITH COLLES' FRACTURE.

By E. M. MOORE, M.D.,

ROCHESTER, N. Y.

(A Paper read before the Medical Society of the State of New York, Feb. 4, 1880.)

It is now just ten years since I read a paper before this Society upon "a luxation of the ulna not heretofore described." The claim of originality in a matter of this kind, at this late day, was too great to be readily admitted, and it is a mild statement to say that it was received with incredulity. It will be recollected that my observation was founded on one case only, that of Mary Tumey, who sprang from a third-story window in a paroxysm of mania, and was instantly killed, making a few respirations for about twenty minutes. Both wrists were broken, and the spine opposite the second and third dorsal vertebræ was crushed. The examination of one wrist revealed, to my astonishment, the peculiar break and entanglement which I have described. Amazed at the result, which was not comprehended in its fulness at first, I proceeded to the dissection of the other wrist, and found precisely the same condition, with the exception of the line of fracture of the radius, one being nearly transverse, and the other quite oblique. The luxation of the ulna presented the same form of rupture of the lateral ligament, from the styloid process, with the same entanglement of the annular ligament. To my report it has been replied that there have always existed irregular luxations, that were not to be regarded as capable of classification. A regular luxation, so called, is one where the joint surface that is separated from its proper connections, is held in its abnormal but definite position, in obedience to definite forces. People do not often spring from third story windows, and this case, like the cause, is abnormal. This cavil, more specious than just, served to satisfy the conservative, and check further inquiry. The fracture of the radius close by the joint is one of the most common, and usually occurs from a fall upon the level ground, or from a step. This presents often very great, and heretofore insurmountable difficulties of restoration. Since the observation of the case of Mary Tumey, I have had far greater success in the management of these fractures, for I have relied upon the relation of the two conditions that I found in the autopsy of Mary Tumey, and that resulting from a fall on the level surface, as being similar, in consequence of the similarity of the appearance of the wrist. I, nevertheless, quite agree, that we must not insist upon appearance, and diagnosis founded upon it, without proof from dissection. Now, patients do not die from the circumstance of falling over on the hand. The combination of circumstances that would destroy life, and leave us with a definite force of this kind, must recur at very remote intervals of time. Great violence must occur in the cases where we can get autopsies, although the force at the wrist might not be more than common in Colles' fracture.

The doctrine I have taught my classes for the last ten years may be succinctly stated. The fall comes upon the palm of the hand, and the radius which sustains the full force of the strain gives way at a point near the wrist. The line of fracture is usually an oblique one, starting from a point on the anterior aspect of the radius, near the articulation, and running backward and upward, making the posterior surface of the lower fragment longer than the anterior. It is seldom more than an inch from the joint, and seldom so far. But the line of fracture is very various, sometimes simple and nearly transverse, but often comminuted to the last degree. The luxation of the ulna exists in more than half of the cases. I now feel quite sure, though I cannot demonstrate it by dissection, that a proper observation of the relation of the head of the ulna to the carpus will make a just diagnosis of its luxation or non-luxation. The force of the fall may be just balanced by the strength of the radius, but in the nature of such accidents this would not be often the case. In most, there would be some force still to be borne. Upon what structures does this fall? The radius instantly, on fracture, ceases to afford resistance, the hand is carried still further back, and then comes the strain on the attachments at the end of the ulna. It will be remembered that the ulna does not articulate with the wrist, but there is a distinct synovial cavity between its head and a strong membrane called the triangular fibro-cartilage. This membrane takes an origin from the rim and side of the radius, and, covering the head of the ulna, is inserted in the pit at the root of the styloid process. As the hand, with its broken fragment of the radius, is forced backward, the strain is often sufficient to rupture the connection between the two bones or to break the ulna near the head. I have seen this double fracture twice only. The rupture takes place at the weakest point, which is its insertion in the pit at the root of the styloid process. But this is not the only resistance. The styloid is held to the carpus by the internal lateral ligament, which takes a very firm hold upon the end and radial surface of the styloid. This also gives way, and usually does so in a peculiar manner—viz., by pulling off the surface of the bone, which proves to be weaker than the ligament. Thus the remaining styloid is brought to an edge like a gouge-chisel, and is shortened about one-half. When these resisting forces are disposed of, the end of the ulna, now laid bare, is pressed against the posterior annular ligament, and is apt to become engaged upon it either by a fold, or, what is more likely, by splitting its fibres and hooking upon it. If very great violence has been used in the production of these lesions, the head of the ulna will be driven forward through the annular ligament and skin, thus producing a compound luxation. These opinions were urged by me upon the profession, chiefly in consequence of the autopsy of Mary Tumey, but also from the very greatly improved results of treatment founded on these views. But I waited for further proof with no little impatience. The next case that goes to confirm the views I have brought forward, was one that proved the luxation by thrusting the head of the ulna through the skin. I report the case:

John O'Hara, æt. 40, a laborer in a lumber yard, fell from a lumber pile eleven feet high, striking with his outstretched hand on a plank road-way. The force was so great as to break the radius just above the wrist, also at its middle, and to dislocate it forward at the elbow. As might be supposed, the radius was much shortened. The ulna was freed from its attachments, as has been described, and pushed through the skin. In this condition the case was presented to me. I removed the end of the ulna with a saw, dressed the fracture, and reduced

the luxation at the elbow. The patient made a slow recovery, but finally obtained very good use of the arm. This bone I now present.

It is absolutely as first found. This adds another, now the third case, where the triangular fibro-cartilage and lateral ligament were torn off in precisely

FIG. 1.

the same manner; the two in Mary Tunney being only engaged in a rupture of the posterior annular ligament, and this one carried entirely through the ligament and skin. But it will be remembered that the two in Tunney's case were only accompanied with the ordinary fracture of the radius at the lower end, and only one fracture in each arm. Where the luxation of the ulna was compound, the radius was enormously shortened by two fractures and luxation at the elbow.

A case of this like O'Hara's has the full value of an autopsy, for the end of the ulna is in our hands, and the fracture can be diagnosticated without failure. I think, in view of the fact that the fractures in the case of Tunney were only of the ordinary character of those styled Colles', with a good deal of the peculiar deformity, that the mode of luxation found here may be fairly concluded to occur from apparently slighter forces, but which are sufficient to break the bone. But I now present you a specimen which, in a singular way, leaves no chance for argument or cavil with reference to the ability of the apparently moderate force to produce the luxation I describe. I am indebted for this to my friend, Dr. Thos. Collins, of Rochester, who was called to see a farmer, who, attempting to get out of his wagon, slipped from the hub, falling upon his hand. Upon examination, the radius was found to be broken, and the ulna was protruded through the skin. An attempt was made to reduce the luxation, but, to his surprise and that of his counsel, Dr. J. F. Whitbeck, it was found impossible to reduce it. Therefore it was sawn off, and the fracture dressed. I might add at this point that he made a good recovery, acquiring as good use of the arm as before the latter accident.)

FIG. 4.

FIG. 3.—1, End of ulna, sawed surface; 2, crust of eburnation.

FIG. 4.—1, Crust of eburnation; 2, obliterated articular surface covered with tags of fibrous tissue.

I now present this specimen. Upon inspection, it will be seen that it presents a very extraordinary appearance. The shaft of the ulna is apparent, but the side and part of the end is covered with as fine a specimen of eburnation as it is possible to produce. The extremity of the ulna exhibits, instead of a smooth articulating surface, a rough one made up of ruptured tags of cicatricial tissue. Inquiry revealed the fact of an antecedent fracture of the radius sixteen years before. The case, as rendered by Dr. Collins, is as follows:

Jacob Winslow, æt. 75, received the injury as above described Oct 2d, 1873. In the year 1857, while walking in a saw mill yard he stepped on a slab and fell over on his hand, producing Colles' fracture. The mode of treatment at this time is unknown. There can be but one inference from this case. We have, by the complete disappearance of the articulating surface, unmistakable proof of antecedent luxation. The eburnation also shows the effect of long and severe friction upon the side, the result of the severe and protracted labor of a farmer's life. The return of the luxation was attempted and failed in consequence of the extreme projection of the ulna, due to the antecedent accident. Several years elapsed without further proof derived from autopsy. But another case, resembling Mary Tunney's, occurred on the 11th of October, 1879.
